Kessler reported a prevalence of 0.24 to 0.3% with a sex ratio of female to male of 1.18:1. Yamada and associates reported a 3:1 female-to-male ratio among their patients from Japan. Hwu and colleagues reported the lifetime prevalence of 0.48% in cities, 0.67% in townships, and 0.33% in rural villages. The gender ratios were not significantly different in their studies. Someya and colleagues reported that persecutory type of delusional disorder was more common (64%) followed by jealous type at (19%) in their cohort.

Yamada and associates (1998) reported that persecutory type was most common at 51% followed by somatic type at 27.5% and jealous type at 147%. Both Yamada’s and Hsiao’s group did not find significant differences in the frequency of subtypes of delusional disorder between the sexes. Depressive symptomatology was present in 43% of the patients at their first visit (Hsiao et al. 1999). Higher frequency of depression has been reported by others at 51%. Both, depression before the onset of delusions and after the onset of delusions have been reported. The subgroup of patients who have hallucinations may have a poorer outcome depending on the intensity of the hallucinations.

### Course and Prognosis

Though the onset can occur in adolescence, generally it begins from middle to late adulthood with variable patterns of course, including lifelong disorder in some cases. Delusional disorder does not lead to severe impairment or change in personality, but rather to a gradual, progressive involvement with the delusional concern. Suicide has often been associated with this disorder. The base rate of spontaneous recovery may not be as low as previously thought, especially because only the more severely afflicted are referred for psychiatric treatment. Retterstol (Retterstol and Opjordsmoen 1991) has provided much information on this. The more chronic forms of the illness tend to have their onset early in the fifth decade. Onset is acute in nearly two-thirds of the cases and gradual in the remainder. In almost half of the cases the delusion disappears at follow-up, improves in 10%, and is unchanged in 31%. In the more acute forms of the illness, the age of onset is in the fourth decade, a lasting remission occurs in over half of the patients and a pattern of chronicity develops in only 10%; a relapsing course has been observed in 37%. Thus, the more acute and earlier the onset of the illness, the more favorable the prognosis. The presence of precipitating factors, married status and female gender are associated with better outcome. The persistence of delusional thinking is most favorable for cases with persecutory delusions and somewhat less favorable for delusions of grandeur and jealousy. However, the outcome in terms of overall functioning appears somewhat more favorable for the jealous subtype. Many believe that treatment nonadherence rather than lack of adequate response to medication is the main reason for persistent symptoms (Manschreck 2006). Some patients require hospitalization, often involuntarily, to prevent harm to themselves or others. Not uncommonly, they may get admitted through the legal system.

### Comorbidities

Depression occurs frequently and is often an independent disorder in these patients.

### Etiology

Etiology of the delusional disorder is unknown. Risk factors associated with the disorder include advanced age, sensory impairment/isolation, family history, social isolation, personality features (e.g. unusual interpersonal sensitivity), and recent immigration. Some have reported higher association of delusional disorder with widowhood, celibacy, and history of substance abuse. Age of onset is later than schizophrenia and earlier in men compared to women.

### Treatment

Though generally considered resistant to treatment and interventions, the management is focused on managing the morbidity of the disorder by reducing the impact of the delusion on the patient’s (and family’s) life. However, in recent years the outlook has been reported to be more optimistic (Manschreck 2006). An effective and therapeutic clinician–patient relationship is important but difficult to establish.

### Somatic Treatment

Overall, treatment results suggest that 81–90% of cases recover either fully or partially when treated with antipsychotic medications. However, limited psychopharmacological data exist regarding treatment of delusional disorder and more would be helpful. Treatment with pimozide was reported to produce full remission in 68% and partial recovery in 22% (N = 143). However, one double-blind, non placebo controlled study with only 7 subjects did not report pimozide to be beneficial. Recent reports suggest that with the introduction of the SGAs and possible concerns about cardiac side effects, pimozide use has dropped considerably. More patients are being treated with clozapine or antipsychotic combinations (Manschreck 2006). There are reports of treatment with FGAs agents with variable success in small number of subjects. SSRIs have been used and reported to be helpful. Pimozide, fluoxetine, and amitriptyline were used in a study with pimozide showing good response. The SGAs showed comparable efficacy to other treatments. In those individuals who do not comply with treatment or are likely to be at risk of hurting themselves or others due to their delusions, long acting antipsychotics administered intramuscularly would be helpful.
Psychosocial Treatment
As mentioned earlier, developing a therapeutic relationship is very important and yet significantly difficult, and requires frank and supportive attitude. Supportive therapy is very helpful in dealing with emotions of anxiety and dysphoria generated because of delusional thinking. Cognitive therapy, when accepted and implemented, is helpful. Confrontation of the delusional thinking usually does not work and can further alienate the patient.

Clinical Vignette 6

Delusional Disorder—Somatic Type
Ms. K is a 32-year-old woman who presented to a dermatology clinic with complaints of “bugs” infecting her fingers, lips, scalp, ears, nose, face, and genitals for the last 3 months. She believed that her husband was the source of infection as she had observed him frequently scratching his scalp. However, she stated her husband feels that “it (her condition) is all in her head.” She noticed others scratching while around her and believed that they had become infested by her presence. She brought multiple samples of the “bugs” in plastic bags.

On physical examination, there were multiple superficial excoriations over her nose, forehead, ears, scalp, jaw, and upper trunk. The dermatologist believed that the patient was suffering from psychogenic parasitosis and reassured Ms. K that her symptoms would be taken seriously and that an entomologist would evaluate her samples. She was prescribed fluocinolone for scalp inflammation, and asked to return to clinic with her husband in 1 week.

Ms. K returned to the clinic with her husband, frantically claiming that “things were falling off” of her and that she always saw “red dots” at the outset of her symptoms. She denied pruritus, scratching, or seeing “bugs.” Her speech was pressured and she was crying. She was upset at her husband for blaming her symptoms on “nerves.” On examination, she demonstrated numerous, crusted bloody excoriations, and her pubis was shaved smooth. Her husband was also examined, and no suspicious lesions were noted. The dermatologist spoke to the husband and patient both alone and together. Her husband had excellent insight. Ms. K was reassured and asked to await the results from the entomologist. The entomologist’s report contained skin debris and some incidental insect parts (Culicoides species, which are not associated with dermatoses). Ms. K continued to worsen over the next several clinic visits, despite reassurance by the dermatologist. She also continued to bring in numerous samples and frequently stated that she believed that her husband is the “root of the problem.” She was delusional and displayed poor insight. She refused psychiatric help but agreed to 50 mg intramuscular haloperidol decanoate. The dermatologist was hoping to control symptoms enough to allow psychiatric referral. She improved remarkably following injection and her skin was nearly clear. She did not feel that she was causing others to scratch around her. She also stopped bringing in samples of bugs. Though she demonstrated limited insight, she still felt that her illness was not due to psychiatric issues. She questioned taking medications when “all this started with my husband.” Pimozide was started at 2 mg/day with a plan to gradually increase the dose upwards. Ms. K continued to show improvement in her symptoms but her insight had not improved much so her dose was doubled to 4 mg/day. Six weeks after starting pimozide, Ms. K’s progress halted. She continued to state that her husband was scratching her scalp, which she believed to be the root of the problem. The dermatologist emphasized the success of haloperidol decanoate therapy and recommended it once more, but the patient refused it. Ms. K was instructed to increase the dose of pimozide to 6 mg/day. Numerous phone conversations over the next several weeks revealed that she was probably noncompliant with the prescribed oral medications. She reported a different dosage each conversation and was unable to give the name of her pharmacy on several occasions, nor could she describe the pills. Her delusions and complaints about her husband persisted. Meanwhile, she had seen another physician who treated her with lindane for pediculosis. She finally agreed to visit the psychosomatic clinic. She was seen by a psychiatrist and was diagnosed to have delusional disorder, somatic type. There were no symptoms of mania or depression noted. The anxiety and sleep disturbances associated with delusional thinking were treated with clonazepam. Four days later, Ms. K paged the dermatologist stating that she was much worse and needed to be seen immediately.

She presented to the clinic with her hair matted down with calamine lotion, numerous superficial erosions, and various exogenous particles in her hair, but no parasites or nits were seen. There were serious concerns about her compliance. She refused the haloperidol decanoate injections due to side effects but agreed to visit the psychosomatic clinic again. She became quite erratic with her dermatology and psychosomatic clinic visits. She continued to have delusional thinking and other symptoms. After missing several clinic visits and with possible erratic compliance, she presented to the psychosomatic clinic with symptoms of anxiety and depression. As she was refusing haloperidol and was noncompliant with pimozide, she was switched to olanzapine 5 mg/day. During subsequent visits her husband reported past history of bouts of depression with neurovegetative symptoms possibly meeting the diagnosis of major depressive disorder with psychotic features. Her dose of olanzapine was meanwhile increased to 20 mg/day. She was started on an antidepressant the dose of which was gradually increased. Laboratory examinations for thyroid function tests, folate, and other chemistries were within normal range.

Unfortunately, Ms. K did not comply with medication recommendations, continued to seek the source of infestation, and resisted recommendations for either intramuscular (IM) medications or an inpatient admission. She was lost to follow-up. The last call for the patient came from her veterinarian. The patient had repeatedly brought her dog into the veterinarian’s office, requesting evaluation of the dog. The veterinarian was encouraged to refer the patient back to the psychosomatic clinic, but no further visits ensued.

Clinical Vignette 7

Delusional Disorder—Jealous Type
A 35-year-old male janitor was admitted to a psychiatric hospital after violating a restraining order brought by his wife. The patient firmly believed (contrary to the facts in this case) that his wife was having an affair with someone for the last few years. He reported that he had often...
**Clinical Vignette 7 continued**

noticed his wife speaking softly and pleasantly with someone on the phone and would stop the conversation as soon as he entered the house. His attempts to trace the call were futile, further confirming his suspicion. He had noticed that his side of the bed was often ruffled as if someone had slept on it. He had also noticed that the bedroom window was on occasion open even when he had made sure that it was locked when he left for his night shift. His wife reported that she had caught him sniffing her undergarments and looking for evidence of recent sexual activity. When his wife confronted him, he angrily accused her of infidelity. Her attempts to reassure him by explaining the alleged evidence of infidelity made him even more suspicious. He started having his house under surveillance to detect the alleged lover. When no unusual activity was noticed, he concluded that she had become cautious.

He surprised her on a few occasions by coming home earlier than anticipated, and her not opening the door immediately resulted in further accusations and verbal arguments. He also went to her workplace unannounced. When his wife told him that he was losing his mind and reading too much into benign actions and events, he became infuriated and they had their first physical altercation resulting in police intervention. She refused to press charges the first time but when she was assaulted again, she brought a restraining order against him. She moved in with her mother. He started spying on her activities at her mother’s place and confronted her at her workplace with allegations of having an affair with someone there. She called the police when he assumed a threatening posture toward her resulting in his arrest and subsequent admission to a hospital by court order. He vehemently denied having any psychiatric illness, became very angry with his wife blaming her for his plight, and remained preoccupied with his wife’s alleged infidelity. The psychiatrist interviewed the patient and his wife separately and then spoke with other family members. A diagnosis of delusional disorder, jealous type was reached and he was started on an atypical antipsychotic medication after much discussion about the alternatives to refusal of treatment. The patient’s agitation and the intensity of the delusional thinking decreased but he remained convinced that his wife was having an affair with someone. The patient lacked insight into his illness. His wife started divorce proceedings, which was yet another proof of her scheme to get him out of the way so that she can marry her alleged lover. Following treatment with an antipsychotic agent and individual therapy, though the patient still believed that his wife did have an affair, he did not have thoughts of pursing or hurting her.

---

**Shared Psychotic Disorder**

**Diagnosis**

Shared psychotic disorder is a rare disorder, which is also referred to as shared paranoid disorder, induced psychotic disorder, folie a deux, and double insanity. Jules Baillarger, in 1860, first described the syndrome and called it folie a communiquée, while Lasegue and Falret, in 1877, first described folie a deux.

In this disorder, the transfer of delusions takes place from one person to another. Both persons are closely associated for a long time and typically live together in relative social isolation. In its more common form, folie imposée, the individual who first has the delusion is often chronically ill and typically is the influential member of the close relationship with another individual, who is more suggestive and who develops the delusion too. The second individual is frequently less intelligent, more gullible, more passive, or more lacking in self-esteem than the primary case. If the two people involved are separated, the second individual may abandon the delusion. However, this is not seen consistently. Other forms of shared psychotic disorder reported are folie simultanée, where similar delusional systems develop independently in two closely associated people. Occasionally more than two individuals are involved (e.g., folie a trois, quatre, cinq; also folie a famille) but such cases are very rare. The most common dyadic relationships who develop this disorder are sister–sister, husband–wife, and mother–child. Almost all cases involve members of a single family.

An important feature in the diagnosis is that the person with shared psychotic disorder does not have a preexisting psychotic disorder. The delusions arise in the context of a close relationship with a person who suffers from delusional thinking and resolve on separation from that person.

**Clinical Features**

The key symptom of shared psychosis is the unquestioning acceptance of another person’s delusions. The delusions themselves are often in the realm of possibility and usually not as bizarre as those seen in patients with schizophrenia. The content of the delusion is often persecutory or hypochondriacal. Symptoms of a coexisting personality disorder may be present, but signs and symptoms that meet criteria for schizophrenia, mood disorders, and delusional disorder are absent. The patient may have ideation about suicide or pacts about homicide; clinicians must elicit this information during the interview.

**Epidemiology**

More than 95% of all cases of shared psychotic disorder involve two members of the same family. About a third of the cases involve two sisters, another one-third involve husband and wife or a mother and her child. The dominant person is usually affected by schizophrenia or a similar psychotic disorder. In 25% of all cases, the submissive person is usually affected with physical disabilities such as deafness, cerebrovascular diseases, or other disability that increases the submissive person’s dependence on the dominant person. This condition is more common in people from low socioeconomic groups and in women.

**Course and Prognosis**

Though separation of submissive person from the dominant person should resolve the psychosis, this probably occurs only in 10 to 40% of the cases. Unfortunately, when these individuals are discharged from hospital, they usually move back together.

**Differential Diagnosis**

Malingering, factitious disorder with predominantly psychological sign and symptoms, psychotic disorder due to a general medical condition, and substance-induced psychotic disorder must be considered.

**Etiology**

There are some data that suggest that people suffering from shared psychotic disorder may have a family history
of schizophrenia. The dominant person suffering from this illness often has schizophrenia or a related psychotic illness. The dominant person is usually older, more intelligent, better educated, and has stronger personality traits than the submissive person, who is usually dependent on the dominant person. The affected individuals usually live together or have an extremely close personal relationship, associated with shared life experiences, common needs and hopes, and often, a deep emotional rapport with each other. The relationship between the people involved is usually somewhat or completely isolated from external societal cultural inputs. The submissive person may be predisposed to a mental disorder and may have a history of a personality disorder with dependent or suggestible qualities as well as a history of depression, suspiciousness, and social isolation. The dominant person's psychotic symptoms may develop in the submissive person through the process of identification. By adopting the psychotic symptoms of the dominant person, the submissive person gains acceptance by the other.

**Treatment**

The initial step in treatment is to separate the affected person from the source of the delusions, the dominant individual. Antipsychotic agents may be used if the symptoms have not abated in a week after separation. Psychotherapy with the nondelusional members of the patient's family should be undertaken, and psychotherapy with both the patient and the person sharing the delusion may be indicated later in the course of treatment. To prevent redevelopment of the syndrome the family may need family therapy and social support to modify the family dynamics and to prevent redevelopment of the syndrome. Steps to decrease the social isolation may also help prevent the syndrome from reemerging.

---

**Clinical Vignette 8**

**Folie a Quatre**

Four members of a large Nigerian family presented with shared persecutory and religious delusions. The first to exhibit symptoms and therefore the presumptive inducer was a 25-year-old midwife (LM) with a 5-year history of persecutory delusions exacerbated in the year before presentation when her family refused to allow her marriage plans. She had become increasingly suspicious and accused others of being witches threatening her family. Attempts to help her with herbal medicines prescribed by a traditional healer, confirmed her delusions of being poisoned. She ate and slept little, and become socially isolated. She also became increasingly argumentative, verbally and physically aggressive, and preoccupied with religious observances. She was well dressed and covered her head with a white veil to signify purity. She held a Bible in her hand and gave "greeting in Jesus' name." Although calm and coherent, she frowned throughout the interview. She accused her relatives of planning with evil forces to eliminate her. She admitted seeing visions of her brother being anointed by the Holy Spirit.

Her brother (DM), older sister (TM) and 15-year-old niece (NM, TM's daughter) all gathered with other members of the family to pray for her. These three were subsequently noticed to be expressing the same persecutory and religious ideation. Their mother and other family members were extremely concerned to find appropriate treatment for the four. DM had worked intermittently as a schoolteacher and his presentation was very similar to LM. He also believed that his mother and older brother were witches who had collaborated with his wife to kill him by taking him to the traditional healer. He was argumentative, irrational but coherent, and expressed the belief that forces were pulling blood from his legs and other relatives were plotting to kill him. Both TM and NM expressed the same delusional thinking that others were planning to kill them all.

All four were admitted to their local psychiatric hospital but DM and LM failed to improve and were transferred to another hospital. Following their transfer, FM and NM made rapid recoveries and were discharged. DM and LM required higher doses of conventional antipsychotic agents and were commenced on depot injections. Attempts were made to separate LM from her brother. Despite this, they continued to meet and prayed incessantly together. They continued to express their shared persecutory beliefs, but after about 3 weeks of treatment their mental state had begun to improve and the pair spent less time together. After 8 weeks both were well enough for discharge and outpatient follow-up on depot medication. LM was subsequently able to return to work and DM enrolled for a course in a theological college.

**Clinical Vignette 9**

**Folie Simultanee (Shared Psychotic Disorder)**

Twin A, a 30-year-old white female who had no previous psychiatric problems, was admitted to a psychiatric ward following a serious suicide attempt. Six months before admission, twin A and her husband found a sperm-filled condom in their bathroom after returning from an evening out. They were concerned that their babysitter had sexually abused their children, although there was no visible evidence.

Shortly thereafter, twin B, who lived in a neighboring city, sent twin A information on ritualistic sexual abuse by satanic cults. The twins then began meeting together and reading literature on satanic worship and ritualistic sexual abuse by satanic cults. Over time, the twins gradually reduced their social activities except for a few specific meetings. They attended support groups for parents of ritually sexually abused children and were convinced that increasingly more people were involved in satanic cults. Within the month before admission, they believed that the satanic cult involved their husbands, family members, neighborhood, church, and the police department. They believed that their children were forced to drink urine and to witness child sacrifice. They also believed that the children were ongoing victims of ritualistic sexual abuse and torture by means of having their feet dipped in hot water.

Several days before admission, the twins met together to view a four-part television series on satanic worship. This resulted in further "hysteria" between the two and the creation of a suicide pact. The evening prior to admission, twin B was brought for evaluation at the hospital. When twin A learned that twin B was at the hospital, she believed that the satanists had abducted her. This prompted a suicide attempt with her partially severing her carotid artery. She experienced a massive hemorrhage, requiring 10 units of packed red blood cells before surgical repair.

(continues)
Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 and DSM-IV-TR criteria sets for schizophrenia are similar in many important ways although not identical. The ICD-10 Diagnostic Criteria for Research provide two ways to satisfy the criteria for schizophrenia: having one Schneiderian first-rank symptom or having at least two of the other characteristic symptoms (hallucinations accompanied by delusions, thought disorder, catatonic symptoms, and negative symptoms). In contrast to DSM-IV-TR which requires 6 months of symptoms (including prodromal, active, and residual phases), the ICD-10 definition of schizophrenia requires only a 1-month duration thereby encompassing the DSM-IV-TR diagnostic categories of both schizophrenia and schizoaffective disorder. Thus, cases of DSM-IV-TR schizoaffective disorder are diagnosed in ICD-10 as schizophrenia.

The DSM-IV-TR and ICD-10 definitions of schizoaffective disorder differ with regard to the relationship of the schizoaffective disorder category with the category mood disorder with psychotic features. In DSM-IV-TR, the differentiation depends on the temporal relationship between the mood and psychotic symptoms (i.e., mood disorder with psychotic features is diagnosed whenever the psychotic symptoms occur only in the presence of a mood episode, regardless of the characteristics of the psychotic symptoms). In contrast, the ICD-10 definition of schizoaffective disorder is much broader. It includes situations in which certain specified psychotic symptoms (i.e., thought echo, insertion, withdrawal, or broadcasting; delusions of control or passivity; voices giving a running commentary; disorganized speech, catatonic behavior) occur even if they are confined to a mood episode. Therefore, many cases of DSM-IV-TR mood disorder with mood-incongruent psychotic features would be considered to be schizoaffective disorder in ICD-10. Furthermore, the ICD-10 definition suggests that there should be an “approximate balance between the number, severity, and duration of the schizophrenic and affective symptoms.” For delusional disorder, the ICD-10 Diagnostic Criteria for Research specify a minimum 3-month duration in contrast to the 1-month minimum duration in DSM-IV-TR.

In contrast to the single DSM-IV-TR category brief psychotic disorder, ICD-10 has a much more complex way of handling brief psychotic disorders. It includes criteria sets for four specific brief psychotic disorders that differ based on types of symptoms (i.e., with or without symptoms of schizophrenia) and course (i.e., whether they change rap-

Finally, the ICD-10 and DSM-IV-TR definitions of shared psychotic disorder are almost identical.

Diagnosis

Definition and Diagnostic Features

Depression conceptualizes a variety of psychic and somatic syndromes, and the diagnosis is derived from diligent clinical observation. Despite intensive biologically oriented psychiatric research the etiology of depressive disorders is still far from being fully understood, and a multifactorial genesis is assumed. Besides psychological and social factors, biological variables apparently play a prominent role, but to date there is not a single biological or genetic test for specifically establishing the diagnosis of depression.

Depression as a term in popular use is mostly considered to be synonymous with low mood or grief. Depression as a mental (and medical) disorder, however, is different, and, besides low mood, is characterized by a variety of additional symptoms. Different depressive syndromes are classified within diagnostic entities using operationalized diagnostic systems such as the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000a) or the International Statistical Classification of Diseases and Related Health Problems, Tenth Revision (ICD-10) (World Health Organization 1992). According to DSM-IV-TR, five of nine symptoms, characteristic of depression, have to be present for a diagnosis of an episode of a major depressive disorder (MDD), see the DSM-IV criteria sets below. This term is often used synonymously with unipolar depression to distinguish it from a major depressive episode as part of bipolar disorder.

The first DSM-IV-TR core symptom is depressed mood during most of the day. This can be expressed by sadness, but may also be expressed as a feeling of emptiness or, in children or adolescents, as irritable mood. This draws a clear distinction between depression and grief or bereavement (characterized in DSM-IV-TR V62.82). As with the other core symptoms, this symptom counts toward the diagnosis of depression if it is indicated by patient’s report or observation. The other psychological core symptoms are markedly diminished interest or pleasure in all or almost all activities, fatigue or loss of energy every day, and disorders of thought and thinking (both the formal aspects of thinking and the ability to concentrate and make decisions) as well as the content which is often characterized by feelings of worthlessness or inappropriate guilt, perhaps combined with hopelessness and recurrent suicidal thoughts. DSM-IV-TR also mentions three somatic or behavioral core symptoms: significant weight loss or decrease in appetite, insomnia or hyposomnia, and psychomotor agitation or retardation.

Both psychological and somatic consequences of MDD have to be taken into consideration when making a diagnosis and formulating a treatment plan. The diagnosis is not always obvious; many patients do not complain about bad mood but visit their general practitioner because of feeling unwell, poor appetite, feeling tired, or having difficulty concentrating on their work. These patients often undergo extensive somatic diagnostic procedures before depression is detected as the underlying cause.

Even if the depressive syndrome fails to fulfill DSM-IV-TR criteria for MDD, it regularly requires

Mood Disorders: Depression

Major Depressive Episode
Major Depressive Disorder, Single Episode
Major Depressive Disorder, Recurrent

Heinz Grunze¹
Cornelius Schüle²
David Casey³
Thomas C. Baghai²

¹School of Neurology, Neurobiology, and Psychiatry, Newcastle University, Newcastle-upon-Tyne, UK
²Department of Psychiatry and Psychotherapy, Ludwig-Maximilians University, Munich, Germany
³Department of Psychiatry and Behavioral Sciences, University of Louisville School of Medicine, Louisville, KY, USA

In addition, patients often consult their family practitioner first for somatic complaints, unaware that these are part of a depressive syndrome. As a consequence, these patients are more likely referred (or refer themselves) to general practitioners or specialists in internal medicine rather than to psychiatrists. The majority of depressive patients can be diagnosed and treated by general practitioners. To enable primary care physicians to diagnose these patients correctly, the PRIME-MD Patient Health Questionnaire (PHQ-9) (Nease Jr. and Maloin 2003) or even more simplified screening questions may be used. A primary care physician may be in a better position than a psychiatrist to treat depression as he or she oversees the overall medical condition of the patient which may include other ongoing medical illness with the potential of drug–drug interactions. However, expert consultation should be mandatory when the depressive syndrome does not improve within 8 weeks of initial treatment or is very severe and complicated by suicidality.

After the diagnosis of depression has been secured, the level of symptom severity, functional impairment and the impact on quality of life should be assessed. Interviewing not only the patient but also the relatives is helpful to obtain a full clinical picture at the beginning of treatment. Recent guidelines recommend for minor depression a course of psychotherapy as first line treatment (National Institute for Health and Clinical Excellence 2004), but additional pharmacotherapy may be needed. Minor depression (also named “subthreshold” or “subsyndromal” depression) results often in substantial health care use, and constitutes a profoundly increased risk of developing major depression (Cuijpers et al. 2004). Community studies using DSM-IV-TR criteria for minor depression show point prevalence rates ranging from 5% to 10% (Kessler et al. 1997).

### Assessment

The diagnosis of depression is an observational, clinical diagnosis. Structured interviews, such as the Structured Clinical Interview for DSM-IV-TR Disorders (SCID), may be helpful to secure the diagnosis of an MDD but it is time consuming. The shorter Mini International Neuropsychiatric Interview (MINI) can help to generate reliable diagnoses.

However, almost by definition, these structured interviews which are designed for MDD overlook minor depression. Relying only on a structured interview for MDD and neglecting the overall clinical impression may thus drive the diagnostic procedure in the direction of somatic discomfort.

**DSM-IV-TR Criteria (296.XX)**

#### Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

**Note:** Do not include symptoms that are clearly due to a general medical condition, or mood-incongruent delusions or hallucinations.

1. Depressed mood most of the day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). **Note:** In children and adolescents, can be irritable mood.

2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).

3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. **Note:** In children, consider failure to make expected weight gains.

4. Insomnia or hypersomnia nearly every day.

5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).

6. Fatigue or loss of energy nearly every day.

7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach of guilt about being sick).

8. Diminished ability to think or concentrate, or indecisiveness nearly every day (either by subjective account or as observed by others).

9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or suicide attempt or a specific plan for committing suicide.

B. The symptoms do not meet criteria for a mixed episode.

C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or general medical condition (e.g., hypothyroidism).

E. The symptoms are not better accounted for by bereavement, i.e., after the loss of a loved one, the symptoms persist for longer than 2 months or are characterised by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

Major Depressive Disorder, Single Episode
A. Presence of a single Major Depressive Episode.
B. The Major Depressive Episode is not better accounted for by Schizoaffective Disorder and is not superimposed on Schizophrenia, Schizotypal Disorder, Delusional Disorder, or Psychotic Disorder Not Otherwise Specified.
C. There has never been a Manic Episode, a Mixed Episode, or a Hypomanic Episode.
Note: This exclusion does not apply if all of the manic-like, mixed-like, or hypomanic-like episodes are substance- or treatment-induced or are due to the direct physiological effects of a general medical condition.
If the full criteria are currently met for a Major Depressive Episode, specify its current clinical status and/or features:
Mild, Moderate, Severe Without Psychotic Features/
Severe With Psychotic Features
Chronic
With Catatonic Features
With Melancholic Features
With Atypical Features
With Postpartum Onset
If the full criteria are not currently met for a Major Depressive Episode, specify the current clinical status of the Major Depressive Disorder or features of the most recent episode:
In Partial Remission, In Full Remission
Chronic
With Catatonic Features
With Melancholic Features
With Atypical Features
With Postpartum Onset

Major Depressive Disorder, Recurrent
A. Presence of two or more Major Depressive Episodes.
Note: To be considered separate episodes, there must be an interval of at least 2 consecutive months in which criteria are not met for a Major Depressive Episode.
B. The Major Depressive Episodes are not better accounted for by Schizoaffective Disorder and are not superimposed on Schizophrenia, Schizotypal Disorder, Delusional Disorder, or Psychotic Disorder Not Otherwise Specified.
C. There has never been a Manic Episode, a Mixed Episode, or a Hypomanic Episode.
Note: This exclusion does not apply if all of the manic-like, mixed-like, or hypomanic-like episodes are substance- or treatment-induced or are due to the direct physiological effects of a general medical condition.
If the full criteria are currently met for a Major Depressive Episode, specify its current clinical status and/or features:
Mild, Moderate, Severe Without Psychotic Features/
Severe With Psychotic Features
Chronic
With Catatonic Features
With Melancholic Features
With Atypical Features
With Postpartum Onset
If the full criteria are not currently met for a Major Depressive Episode, specify the current clinical status of the Major Depressive Disorder or features of the most recent episode:
In Partial Remission, In Full Remission
Chronic
With Catatonic Features
With Melancholic Features
With Atypical Features
With Postpartum Onset
Specify:
Longitudinal Course Specifiers (With and Without Interepisode Recovery)
With Seasonal Pattern
illness-related disability. For the US, the National Comorbidity Survey found a lifetime prevalence of MDD, as defined by the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) criteria, of 17% (Blazer et al. 1994). Globally, however, epidemiologic studies of depression show considerable variation across and within countries, to a large extent due to the cross-cultural unsuitability of assessment instruments. The International Consortium of Psychiatric Epidemiology interviewed 37,000 adults in 10 countries (in North America, South America, Europe, and Asia) using the WHO Composite International Diagnostic Interview (Kessler et al. 2003). The life time prevalence of depression for adults varied from 3% in Japan to 16.9% in the US, with most countries in the range between 8% and 12% (Andrade et al. 2003). For the US, the mean duration of depressive episodes was 16 weeks and about 90% of the patients were suffering from moderate to severe forms of depression causing marked role impairment (Kessler et al. 2003). Minor depression may be much more frequent: a South American study on the presence of depressive symptoms reported extremely high prevalence rates of up to 72.6% (Rodriguez and Puerta 1997). These numbers indicate not only the potential impact of psychosocial and cultural factors on the manifestation of depression but also the methodological difficulties in generating reliable statistics.

A family history of mood disorder is associated with a younger age at onset of depression (Nierenberg et al. 2007). Age and gender affect both the prevalence and the consequences of depression: women are twice as likely as men to be affected (Kessler 2003). Younger age at onset and female gender are positively correlated with suicidality including suicide attempts. Completed suicide, however, seems to be equally distributed between genders in most countries.

The importance of depression is heightened by the prediction that the prevalence of depressive disorder will increase in the years to come (Sartorius 2001). The WHO estimates that depressive disorders will be the second most frequent cause of disability in industrialized countries by the year 2020. The reasons include demographic factors (e.g., increased life expectancy at all ages), better chances of survival of people with chronic diseases often comorbid with depression, iatrogenic effects (e.g., use of medications likely to increase the rates of depression, e.g., corticosteroids), risks intrinsic to social changes (such as diminished family care and increasing numbers of people living alone) and increasing levels of stress due to growing occupational demands observable in many countries.

Comorbidity Patterns
Frequently, depression does not stand by itself but occurs as a psychological or biological consequence of a somatic or psychiatric disorder. Here we deal only with the most frequent comorbidity patterns.

Depressive Disorders with Comorbid Psychiatric Disorders
Comorbidity of depressive disorders with other psychiatric disorders is common and significantly affects treatment outcomes. Greater numbers of concurrent comorbid conditions are associated with increased severity, morbidity, and chronicity of depressive disorders (Rush et al. 2005).

Anxiety Disorders
A lifetime prevalence of more than 40% for comorbid anxiety disorders, namely panic disorder, phobias, and generalized anxiety disorder, has been reported in patients suffering from depressive disorders (Hasin et al. 2005), but it is not clear whether both diagnostic entities can be separated, or represent a mixed anxiety–depression syndrome. Patients with comorbid MDD and panic disorder show a greater severity of syndromes in comparison to patients suffering from MDD alone (Grunhaus et al. 1994).

Comorbid anxiety disorders may reduce the effectiveness of an antidepressant, as suggested by a small case series of patients treated with divergent tricyclic antidepressants (TCAs), most with imipramine or phenelzine (Grunhaus et al. 1986). Using antidepressants with proven efficacy in both MDD and anxiety disorders, for example, selective serotonin reuptake inhibitors (SSRIs) and some selective serotonin-noradrenergic reuptake inhibitors (SNRIs), together with concomitant specific psychotherapies seems to be a sensible strategy.

Substance Abuse
Abuse and addiction to alcohol, nicotine, and other drugs are often accompanied by depression, with a lifetime comorbidity of 40%, 30%, and 17%, respectively, in one survey (Hasin et al. 2005). Depressed patients with comorbid substance abuse are more likely to have an earlier age of onset of depression, more depressive symptoms, a greater functional impairment, and a history of more previous suicide attempts than patients with depression alone (Davis et al. 2006). Because pharmacokinetic and pharmacodynamic drug interactions, for example, between phenylpiperidine opioids and SSRIs (Aliwadhi et al. 2007), and the psychosocial consequences of drug abuse both have significant impact on response and recovery rates from depressive disorders, a combined therapeutic approach addressing the depression and any comorbid condition is mandatory. This is especially true for psychotherapeutic and psychosocial approaches, but is also relevant for pharmacotherapy, for example, by choosing antidepressants with lower pharmacological interaction potential, for example most SSRIs, or some selective noradrenergic reuptake inhibitors (NARI) and dual action antidepressants.

Personality Disorders
At least one-third of depressed patients fulfill the diagnostic criteria of a personality disorder, most commonly obsessive–compulsive (16%), paranoid (10%), and schizoid (7%) personality disorders (Hasin et al. 2005). It has been estimated that 6% of depressed patients also display features of Borderline Personality disorder (BPD) (Depression Guideline Panel 1993). Analyzing psychosocial and biological factors, Gunderson and Phillips (1991) concluded that BPD and depression coexist as independent disorders. For the other personality disorders, there is still uncertainty concerning their interdependency with depression.

Surprisingly, the occurrence of depression can be a positive prognostic factor for the treatment of borderline and antisocial personality disorders (Shea et al. 1992), although a higher risk of self-injury has been reported (Shea et al. 1987). However, antidepressant medication is usually less effective and treatment takes longer in patients with
Depressive Disorders with Comorbid General Medical Conditions

Depressive syndromes are frequently present in people with severe and chronic general medical conditions. Slow-progressing illnesses leading irreversibly to severe incapability show a high percentage of comorbid MDD, for example the prevalence of MDD among patients with age-related macular degeneration is approximately 30% (Casten et al. 2004). General medical conditions or their treatment may also be directly responsible for depressive symptoms (Patten and Barbui 2004). If depression is only mild to moderate, an organic factor is etiologically responsible for the depressive syndrome (“organic depression”) and the organic disease can be treated sufficiently, treatment of the medical condition is mostly sufficient (e.g., substitution of thyroid hormones in case of hypothyroidism). However, with severe depression including suicidal ideation, additional symptomatic antidepressant treatment becomes mandatory. The same is true when the organic factor cannot be treated due to other conditions (e.g., discontinuation of immune system suppressors after transplantation). Possible organic causes for depressive syndromes are summarized in Table 66–1.

Cardiovascular Disorders

A variety of studies confirm the interconnection between medical disorders and the risk for developing depressive symptoms either as adjustment disorder or MDD. An exceptionally high comorbidity of depressive symptoms and cardiovascular disease (CVD) has been described (Glassman et al. 2006, Purebl et al. 2006), but depression is rarely diagnosed in patients suffering from CVD in routine clinical settings. Comorbid MDD worsens the outcome of coronary heart disease or a myocardial infarction, especially in treatment-refractory depressed patients (Carney et al. 2004). Depression by itself, especially MDD, enhances cardiovascular mortality independently of other cardiovascular risk factors (Penninx et al. 2001). An important biological predictor of cardiac complications may be disinhibition of Hypothalamic-Pituitary-Adrenal (HPA) axis activity which occurs in the majority of MDD (Lederbogen et al. 1999). Both a significantly lowered risk of death or myocardial re-infarction in patients taking SSRIs (Taylor et al. 2005) and a failure to lower cardiac risk by antidepressant treatment (Berkman et al. 2003, Shimbo et al. 2005) have been reported. Medications should have a drug–drug interaction risk as low as possible and should not interfere with cardiac conductance, rhythm, or output. Most modern antidepressants, including SSRIs, NARI, and dual-action substances fulfill these criteria. In addition, Q2 fatty acids have been described as having cardioprotective effects as well as potential antidepressant properties, (Frasure-Smith et al. 2004) and thus may be considered as an additional option in these patients.

Endocrinological Disorders and Diabetes Mellitus

Depression is a risk factor for type II diabetes mellitus and a bidirectional positive association has been assumed (Evans et al. 2005). MDD may impact negatively on therapeutic adherence with a subsequent risk for vascular complications. Vice versa, hypercortisolism during MDD may facilitate the onset of diabetes. Antidepressant treatments show similar effectiveness in diabetic patients, however, some antidepressants and antipsychotics with sedating properties may facilitate weight gain. This may contribute to a metabolic syndrome worsening a preexisting diabetes mellitus or facilitating a switch from a prediabetic syndrome to diabetes (American Diabetes Association 2005).

Renal Disorders

Having a severe acute or chronic renal disease predisposes to an adjustment disorder with marked depressive syndromes (Kimmel and Peterson 2005) or an MDD. Besides psychotherapeutic support, antidepressant pharmacotherapy may become necessary. Renal failure with consecutive diminished renal clearance may exaggerate the side effects and toxicity of antidepressants, necessitating a dose adjustment.

</table>

Half of the standard dose is usually recommended when starting treatment and the use of antidepressants with low potential to interact with other drugs via the cytochrome P-450 system, such as sertraline or citalopram. Frequent evaluation of side effects and blood level monitoring help prevent overdosing. If renal failure progresses and hemoperfusion or hemofiltration becomes necessary, antidepressant plasma levels may fall and dose adjustment may be required.

**Hepatic Disorders**

Patients suffering from chronic hepatitis experience an enhanced risk for developing depression, especially those receiving interferon treatment. Patients with a history of depression may even require prophylactic antidepressant treatment when starting interferons (Schaef er et al. 2002). Treatment of comorbid depression and hepatic disorders requires specific precautions. Antidepressants rank fifth of drugs causing liver damage (Andrade et al. 2005). TCAs, irreversible inhibitors of monoamine oxidase inhibitor (MAOI) A and B and nefazodone seem to have higher hepatotoxicity than other agents, such as SSRIs (Lucena et al. 2003). SSRIs or other modern antidepressants still require a dose of adaptation in patients with hepatic disorders owing to reduced clearance of the drugs and their metabolites and, therefore, prolonged elimination times.

**Infectious Disorders**

Viral or bacterial infections are often accompanied by psychiatric syndromes, frequently depression, which may require specific treatment. Infections of the nervous system, in particular, such as Lyme disease (Fallon and Nields 1994) or neurosyphilis (neurolues) (Pavlovic and Milovic 1999) may provoke psychiatric disorders including MDD. Infection with the human immune deficiency virus (HIV) is highly associated with depression and suicidal behavior (Jin et al. 2006, Porche and Willis 2006) and HIV risk behaviors endangering others occur more frequently with comorbid depression (Hutton et al. 2004).

Hepatitis C-infected patients are also more likely to have psychiatric comorbidities such as depressive disorders (Butt et al. 2006). Finally, treatments directed against infections such as interferons or antibiotics may increase the risk of developing depressive symptoms.

**Neurological Disorders**

Depression is a relatively common psychiatric comorbidity of most neurological disorders, with prevalence rates ranging between 20% and 50% among patients with epilepsy, stroke, dementia, Parkinson’s disease (PD), and multiple sclerosis (Kanner 2005b). In addition, some treatments of neurological disorders (e.g., corticosteroids) enhance the risk for depression as a treatment-related adverse event. Antidepressant pharmacotherapy becomes mandatory in most cases of medium to severe depression accompanying a neurological disorder, but may interfere with the underlying condition, for example, the TCA maprotilline, where a high risk of seizures has been described.

**Epilepsy**

A bidirectional relationship between epilepsy and depression has been delineated (Kanner 2005a). For example, after temporal lobectomies in treatment-resistant epilepsy, patients often experience postsurgical depression and antidepressant pharmacotherapy may become necessary. On the other hand, Spencer et al. (2003) reported relief of depression after respective surgical treatment of epilepsy.

Because even low doses of antidepressants may trigger seizures in patients suffering from epilepsy, starting with the lowest efficacious doses, especially in the case of TCAs, is recommended. Fluoxetine and fluvoxamine exhibit the lowest risk for provoking seizures (Pisani et al. 1999). However, an interaction, especially with carbamazepine, may occur and therefore these combinations should be used cautiously, and be accompanied by monitoring for adverse events and carbamazepine serum levels.

**Stroke and Dementia**

According to a large Danish registry study, severe depression is associated with cerebrovascular disorders as an independent risk factor (Nilsson and Kessing et al. 2004). Conversely, after a stroke, patients often show depressed mood requiring treatment. In placebo-controlled studies, SSRI and NARI have confirmed efficacy in poststroke depression (Rickards 2005). SSRI or TCA treatment during the first 6 months after a stroke significantly increased survival both in depressed and, interestingly, also nondepressed patients (Jorge et al. 2003). Functional recovery and improvement of executive functioning following stroke also seem to be linked to antidepressant treatment (Narushima et al. 2007).

Prophylactic efficacy in preventing poststroke depression has been described particularly for the noradrenergic and selective serotonergic antidepressant (NaSSA) mirtazapine (Ween 2005).

Symptoms of depression in Alzheimer’s disease and other forms of dementia are frequent, but virtually indistinguishable from somatic apathy, loss of drive and affective disturbances. In addition, depressive symptoms seem to be independent risk factors for the later development of Alzheimer’s (Ownby et al. 2006) and a history of depression seems to be associated with a more rapid cognitive decline in patients with Alzheimer’s and pronounced neuropathological changes in the hippocampus (Rapp et al. 2006).

When initiating antidepressants, SSRI, NARI, SNRI, and NaSSA seem to be more favorable than TCA due to their relative lack of anticholinergic side effects.

**PD**

A high prevalence of depression in PD ranging from 20% to 40% (Lieberman 2006) has been described. Depression may frequently precede motor symptoms and the subsequent diagnosis of PD (Schuurman et al. 2002). No controlled studies have been published, but both SSRI and SNRI seems to be well tolerated and efficacious in most cases (Menza et al. 2004). A moderate association of SSRI use and extrapyramidal motor side effects in susceptible patients has been reported (Schillevoort et al. 2002), and an interaction between serotonergic and dopaminergic pathways has been assumed (Lambert et al. 1998). Using the MAO-B inhibitor selegiline (see Section, “MAOI”) both PD symptoms and depression may improve. Although the anticholinergic effects of TCA may be beneficial in PD, other frequent somatic disorders such as concomitant heart disease, prosstatic enlargement, or acute angle-closure glaucoma limit the usefulness of TCAs in this patient group (Cummings and Masterman 1999).
Encephalitis Disseminata/Multiple Sclerosis In addition to signs of behavioral disinhibition such as pathological laughing and crying, an association between multiple sclerosis and depression has been reported (Patten and Metz 1997). Treatment with corticosteroids may additionally contribute to the emergence of a depressive syndrome, and at least in severe cases antidepressant pharmacotherapy may be needed.

Migraine Depression is one of the most frequent comorbid disorders in chronic migraine (Mercante et al. 2005). Vice versa, comorbid migraine has a devastating effect on the quality of life of depressed patients (Hung et al. 2006). When migraine is associated with a depressive disorder, antidepressant pharmacotherapy may not only ameliorate depressive symptoms but also prevent migraine attacks. Both TCA (amitriptyline) and SSRI (fluoxetine) have shown effectiveness in preventing migraine attacks using therapeutic antidepressant dosages (Campo-Arias 2004).

When using triptans for migraine treatment, one should be aware of a theoretically enhanced risk of a serotonin syndrome with concomitant use of SSRI, MAOI, or lithium. However, the reported rate of serotonin syndromes is very low; thus, the cautious use of triptans together with SSRI or lithium seems to be acceptable. MAOI, however, should be clearly avoided (Gardner and Lynd 1998).

Neoplasias and Paraneoplastic Syndromes Depression is frequent in patients suffering from cancer; rates of 19% for depressive symptoms and 8% for MDD have been reported (Wedding et al. 2007). In addition, most chemotherapeutics used in the treatment of cancer may provoke depression.

A comprehensive treatment plan should include all available pharmaco- and psychotherapeutic options and lead to a substantial improvement in quality of life (Miovic and Block 2007). Medications with low toxicity and interaction potential, for example, citalopram, sertraline, or venlafaxine may be advantageous considering other ongoing chemotherapies and potential liver and renal damage.

Course and Subgroups The average age of onset of depression is between 20 and 30 years (Emmeier et al. 2006). A second peak of the age distribution is observed in the elderly. The course of the disorder may be restricted to one episode during one’s lifetime, but in the majority of cases depression is a highly recurrent illness with an average of 8 lifetime episodes (Angst et al. 1995). However, approximately 20–25% of MDD patients experience a chronic, unremitting course and thus constitute a major challenge for treatment (Mueller and Leon 1996).

With the exception of recurrent brief depressive episodes as singled out in the ICD 10 (and included in the research appendix in DSM-IV-TR), the minimum duration threshold for an episode is at least 2 weeks. Shorter durations qualify for minor depression. The differences between MDD and minor depression may not always be very helpful for clinical decision making since it has been shown that minor depression can itself cause significant impairment in some individuals (Cuijpers et al. 2004).

Severity of the Disease Depression can be divided into mild, moderate, or severe. Besides clinical judgment and the diagnostic criteria according to DSM-IV-TR or ICD-10 or the Clinical Global Impression scale (CGI-S, Item I, severity of disease) (National Institute of Mental Health 1976), severity can be classified according to thresholds set using depression rating scales such as the Hamilton rating scale for depression (Hamilton 1960) or the Montgomery-Åsberg rating scale for depression (Montgomery et al. 1979).

This subdivision according to severity is of clinical importance because some guidelines recommend that mild depressive syndromes can be treated with psychotherapy only (National Institute for Health and Clinical Excellence 2004). This will change if there is a history of moderate to severe recurrent depression. In this instance, antidepressants will become a first line treatment in adults, alone or in combination with cognitive behavioral therapy (CBT) (Anderson et al. 2008). In moderate depression, most depressed patients do require the addition of antidepressant medication. In mild to moderate, but not in severe, depression there is a distinct probability of response using phytotherapeutics such as St. Johns wort (Kasper 2001) or benzodiazepines without antidepressants (Laakmann et al. 1996), even if this option is not recommended due to the inherent abuse potential. For severe depression, ECT, TCA, and dual-action substances such as venlafaxine, duloxetine, or mirtazapine may be especially advantageous.

Suicidality About two-thirds of people who commit suicide suffer from depression. Perhaps the most accurate prospective long-term, large cohort study on suicide risk in affective disorders was conducted by Angst et al. who followed up 406 patients with unipolar depression or bipolar disorder from 1963 to 2003 (Angst et al. 2005). By 2003, 11.1% of these patients had committed suicide. This underlines the prominent role of early diagnosis and treatment of depression for suicide prevention.

Dealing with suicidality is probably the greatest challenge in the treatment of depression, both for the psychiatrist and the patient (and, of course, the family). The topic of suicidal ideation needs to be addressed at every contact with severely depressed patients, and careful and sensible questioning is needed. Assessment of suicidality needs both experience and empathy, but proven predictors of an elevated suicide risk that may help guide decisions are severity of depression, history of suicide attempts, suicidal ideation, hopelessness, unemployment, comorbid psychotic disorders, substance abuse, personality disorder, a family history of mental disorders, male gender, and living single due to being widowed or divorced (Brown et al. 2000, Moscicki 1999). Suicide events are most common immediately before treatment initiation and during the interval until treatment becomes effective; during these early phases, doctors should plan frequent follow-up visits and also consider a possible supporting role for family members and caregivers. The short-term use of benzodiazepines, for example, lorazepam, to alleviate mood and lower possible restlessness and agitation, may be useful. In addition, doctors should give patients a realistic view about the duration until onset of improvement; overoptimistic expectations of patients and doctors may result in disappointment and consequently hopelessness and suicidality.

Over the past two decades, there has been controversy as to whether antidepressant treatment may put patients at...
an increased risk of suicide, with conflicting claims being made, especially regarding SSRIs. Antidepressants may decrease suicide rates on a population basis (Ludwig and Marcotte 2005), but at the same time they may increase suicidality (or even suicide events) in some individuals early in treatment (Healy and Whitaker 2003). As recently reviewed by Hall and Lucke (2006) and Möller (2006a, b), there is some supportive evidence for both views (see Section, “Treatment-Emerging Suicide and Suicidality”).

**Depression with Psychotic Features**

Psychotic features of depression such as hallucinations or delusions, for example, delusional hypochondria, feelings of guilt or nihilistic thoughts, are predominantly mood congruent, but may rarely be incongruent with the depressed mood. Psychotic symptoms are in most cases an indicator of the particular severity of depression, including suicide risk. In patients suffering from MDD with psychotic features, a combination of an antidepressant with an antipsychotic medication is usually recommended (Coryell 1996). However, this may not be best for all patients, for example, in elderly patients, the addition of perphenazine to the TCA nortriptyline did not improve efficacy of the treatment in comparison to the TCA monotherapy (Mulssant et al. 2001). ECT has also been recommended as a possible first line treatment in psychotic depression (American Psychiatric Association Committee on Electroconvulsive Therapy 2001).

**Other Clinical Features with Possible Impact on the Course and Treatment Outcome**

**Catatonic Features** Severe psychomotor retardation, stupor, immobility, and, in contrast, severe agitation (sometimes labeled as catatonic features), can be observed in depressed patients (Taylor and Fink 2003). In routine clinical use, sedating antidepressants or combinations of non-sedating antidepressants with sedatives are used in agitated patients, whereas activating substances such as SSRIs or NARI are used in patients with predominant psychomotor inhibition. ECT may also have an excellent effect in these cases (Rohland et al. 1993).

**Melancholic Features** According to DSM-IV-TR, melancholia is characterized by a loss of the ability to feel pleasure and a variety of somatic symptoms and psychomotor alterations. Therapeutic consequences of melancholic features are similar to those for severe depression. Patients are frequently responsive to augmentative strategies, such as the combination with lithium or sleep deprivation.

**Atypical Features** There is no clear agreement about the features that should characterize atypical depression (Fountoulakis et al. 1999). For example, in French-speaking countries, the term “atypical” depression is used for a group of patients with psychotic features. According to DSM-IV-TR, atypical depression is characterized by the presence of at least two of the following criteria: increase in appetite and weight gain, hypersomnia, leaden paralysis, and long-standing pattern of interpersonal rejection sensitivity. The Inventory of Depressive Symptomatology-Clinician Rating (IDS-C30) is suitable for the diagnosis of atypical depression. Patients with atypical depression are more likely to have an earlier age at onset, a greater comorbidity with anxiety symptoms, and greater symptom severity compared with typical depression (Novick et al. 2005). Empirical data favor MAOI and SSRI as first-line treatment options (Henkel et al. 2006).

**Seasonal Pattern** Seasonal affective disorder (SAD), usually during autumn or winter often develops into bipolar disorder later and atypical symptoms as characterized in DSM-IV-TR may occur more frequently.

The strongest evidence for efficacy in SAD is for the SSRI citalopram. There is also preliminary evidence that citalopram prevents relapse while bupropion and CBT prevent recurrence the following season. Bright light therapy (phototherapy) can be used as an early augmentation strategy (see Section, “Nonpharmacological Treatment Strategies”)

**Depressive Syndromes in Pain Conditions**

Depressive syndromes and chronic pain are frequent comorbidity conditions. Approximately 70% of patients with major depression present with physical complaints (Fava 2002, Simon et al. 1999). Somatization disorders, fibromyalgia, and similar conditions with predominant pain are often accompanied by depressed mood. In neuropathic pain accompanied by depression, antidepressants with a mixed serotonergic and noradrenergic mode of action such as the TCA amitriptyline used to be the treatment of choice. More recently, newer antidepressants, especially NARI, NaSSA, and SNRIs, and to a lesser extent SSRI, have shown efficacy in the treatment of pain conditions with and without comorbid depression (Jann and Slade 2007). Taken together, antidepressants with both serotonergic and noradrenergic properties appear to be particularly effective in the treatment of pain and painful physical symptoms, and antidepressants are now considered as an essential medication in therapeutic regimes for pain control.

**Adjustment Disorder with Depressed Mood/ Mixed Anxiety and Depressed Mood**

In mild to moderate adjustment disorders (DSM-IV-TR V 309), psychotherapy alone may be sufficient, whereas with persisting and severe depressive symptoms additional pharmacotherapy may be needed. Although controlled efficacy trials of antidepressants in adjustment disorders are rare, both clinical experience and retrospective studies (Hameed et al. 2005) suggest no difference in response rates to treatment between depression and adjustment disorder with depressive symptoms.

**Dysthymic Disorder and MDD in Combination with Dysthymic Disorder**

Diagnostic criteria for dysthymia and depressive disorders differ as far as the severity and duration of the symptoms are concerned. Dysthymic disorder is characterized by a period of at least 2 years with depressed mood, but having fewer than the five core symptoms of depression demanded by DSM-IV-TR for the diagnosis of MDD. In brief, dysthymic disorder is characterized by a chronic depressive syndrome of lower intensity of symptoms than in major depression, although it produces very similar levels of disability and loss of quality of life. A superimposing major depressive episode can occur in patients suffering from dysthymic disorder, named “double depression.” The differential diagnosis of both disorders is difficult when dysthymic disorder...
follows a depressive episode, because the symptoms of the former are then indistinguishable from MDD with incomplete remission. Only after achieving full remission for at least 6 months, can any subsequent dysthymic symptoms be diagnosed with some confidence as dysthymic disorder.

The acute efficacy of antidepressants in dysthymic disorder is comparable to MDD, although the probability of complete recovery is less (Judd et al. 1998). Early implementation of psychotherapy is therefore recommended.

Recurrent Brief Depression

Recurrent brief depression is characterized by at least monthly depressive episodes of short duration lasting only a few days (Pezawas et al. 2005). Except for the duration, all other criteria for MDD according to DSM-IV-TR are fulfilled, and cooccurrence of MDD and recurrent brief depression is relatively common. So far, there is little evidence supporting pharmacological treatment of recurrent brief depression; most published studies of acute and prophylactic SSR1 treatment are negative (Montgomery et al. 1994).

Differential Diagnosis

If organic factors can be ruled out, as the underlying cause for depressive symptoms MDD still needs to be separated from other mental disorders that show features and symptoms of depression, without fulfilling full DSM-IV-TR criteria for MDD. Dysthymic disorder and adjustment disorder with depressive symptoms have been discussed. The DSM-IV-TR heading “Depressive disorder not otherwise specified” summarizes further depressive syndromes which fall short of the threshold for MDD or dysthymic disorder. These syndromes include recurrent brief depression and minor depression, but also premenstrual dysphoric disorder, postnatal depression, and postsympathetic depressive disorder in schizophrenic patients. In those instances, depression can be conceived as secondary to another somatic condition or psychiatric illness. The treatment of postsympathetic depression has attracted little attention; however, the occurrence of depression after psychosis is frequent (in up to 40% of patients), constitutes one of the most worrisome predictors for a bad functional outcome (Conley et al. 2007) and therefore needs intense treatment. Although the quality of most studies is poor, a meta-analysis is supportive of the efficacy of antidepressants in postsympathetic depression (Whitehead et al. 2002). Furthermore, mood symptoms are common in substance abusers, and can usually be directly related to the intake of illegal drugs. In DSM-IV-TR, they are therefore classified as “organic mood syndrome, depressed type.” They may be transient as a direct action of the substance, or lasting as a consequence of toxic brain impairment. Without knowing the causality, it is often impossible to distinguish mood symptoms due to substance abuse from MDD (Patten and Lamarre 1992). Substance-induced mood symptoms can also occur as a side effect of prescribed medication, for example, reserpine, beta blockers, oral contraceptives, corticosteroids, and some antibiotics.

A depressive episode, fulfilling MDD criteria, can also manifest itself as part of a bipolar or a schizoaffective disorder. It has been suggested that symptoms partially opposite to DSM-IV-TR criteria for MDD, such as increased appetite, weight gain, hypersomnia, or symptoms such as agitation and irritability can be observed more often in depression as part of bipolar disorder. However, a major depressive episode in unipolar, bipolar, and schizoaffective disorders can be virtually indistinguishable. This underlines the importance of having a reliable and detailed history of the patient, and diligent exploration for past (hypo)manic and/or psychotic episodes. If depression is then diagnosed as a part of bipolar or schizoaffective disorder, this might considerably change treatment regimens (see the respective chapters in this textbook).

Differences in Developmental, Gender, and Cultural Presentations

Developmental Presentations

Depression in Children and Adolescents

Depression in preschool children is rare (0.8% point prevalence, (Depression Guideline Panel 1993) but markedly increases during adolescence (4.7% point prevalence (Kashani et al. 1987). The clinical features of depressive disorders in young patients may differ substantially from those of adult patients. DSM-IV-TR explicitly mentions that irritable, not clearly depressed mood may dominate the clinical picture in young patients. In addition, instead of showing other typical depressive symptoms as defined by DSM-IV-TR or ICD-10, depressed children may exhibit mainly behavioral problems that cause difficulties in psychosocial functioning at home or at school. Identifying these behaviors as related to depression requires not only evaluating the patient but also talking to parents and teachers.

Gender differences in symptomatology are already apparent in adolescent depression. Bennett et al. (2005) interviewed 383 depressed adolescents using the Childhood Version of the Schedule for Affective Disorders and Schizophrenia and the Beck Depression Inventory. They found that within this sample, with a mean age of 15.8 years, depressed girls were more likely to exhibit guilt, body image dissatisfaction, self-blame, self-disappointment, feelings of failure, concentration problems, difficulties working, sadness, and depressed mood, fatigue, and health worries than depressed boys. In contrast, depressed boys had higher clinician ratings for anhedonia, depressed morning mood, and morning fatigue.

Treatment recommendations are based on relatively little evidence of efficacy and safety in children and adolescents. It is generally accepted that in mild to moderate depression a course of CBT should be considered as first line treatment for those not responding to initial structured supportive treatment (Anderson et al. 2008). In more severe depression, additional pharmacotherapy may become necessary. So far, 18 placebo-controlled RCTs of newer antidepressants have been conducted, but only 12 have been published. In summary, the evidence about safety and efficacy of SSR1, except fluoxetine, is mixed. TCAs appear modestly more effective than placebo in adolescents but not to a clinically significant degree in children younger than 13 years (Hazell et al. 2002). Analysis of newer antidepressant studies in adolescents and younger children separately shows a significant benefit in the former (10 studies, 62% vs. 49% response, numbers needed to treat (NNT) 7–8) with no significant benefit in the latter (5 studies, 65% vs 58% response, NNT 14) (Bridge et al. 2007). However, studies of
fluoxetine did show similar significant benefit in both age groups (NNT 5). Fluoxetine is the only agent approved by regulatory agencies in the United States, United Kingdom, and Europe for use in depressed youth.

There is reasonable concern about the possibility of increased suicidal behavior in depressed youth treated with antidepressant medications (Leslie et al. 2005). Meta-analyses of RCTs imply that SSRIs increase suicide ideation compared with placebo, but observational studies suggest that SSRIs do not increase suicide risk more than older antidepressants (Hall and Lucke 2006) (see also Section, “Treatment-Emerging Suicide and Suicidality” for the inherent problems in using RCTs to evaluate suicide frequencies and suicidality). While there is no evidence of completed suicide from reported RCTs, compared with placebo, there is a higher incidence of self-harm and aggressive or impulsive actions, especially with paroxetine or venlafaxine treatment. The anxiolytic and activating properties of SSRIs may negatively superimpose on the patient’s predisposition: A Finnish inpatient study showed that suicidal ideation was particularly prevalent among boy patients with conduct disorders who had previously manifested violent acts (Haavisto et al. 2003).

Therefore, when initiating medication, careful monitoring is advised. From a low start, children may be able to tolerate and sometimes require doses similar to those for adults. Particularly in the initial weeks, in addition to monitoring for suicidality, patients and families should be asked about medication compliance and changes in behavior.

**Depression in the Elderly**

In adults, the prevalence of depression appears relatively independent of age (Patten et al. 2001) but a high rate of depressive symptoms requiring treatment in the elderly (Chopra et al. 2005) has been reported. Underdetection of minor depression, which shows a high prevalence in the old age (Horowitz et al. 2005) and requires treatment, constitutes a problem. Subsyndromal depression appears to be especially frequent in general medical treatment settings, for example, up to 30.5% in hospitals and long-term care (Parmelee et al. 1989).

The prevalence of suicidal ideation is relatively high in the elderly (Pfaff and Almeida 2005) and older patients tend to have more and longer major depressive episodes together with more general medical comorbidities (Husain et al. 2005). Finally, a considerable comorbidity exists with dementia, stroke, and PD, putting patients at additional risk for depression (see above).

The response to antidepressant treatment in the elderly may differ slightly from that in younger patients, as antidepressant-placebo differences in RCTs are significantly smaller than in younger adults (NNT 7–8 v 5) (Walsh and Sysko 2005). In addition, relapse rates are higher and the longitudinal outcome is less favorable than for middle-aged adults (Mitchell and Subramaniam 2005). The more adverse longitudinal course in old age may be more due to medical comorbidity, immobility, and psychosocial factors than to age itself.

An interesting question is whether a certain class of antidepressants is more favorable in old age. A Cochrane analysis (Motttram et al. 2006) of 14 RCTs detected no significant differences in efficacy between TCAs, TCA-related drugs, SSRIs, MAOIs, and atypical antidepressants, but more patients withdrew from the trials during treatment with TCAs compared to SSRIs.

Thus, tolerability is an essential consideration when choosing an antidepressant in the elderly. Some side effects, which raise particular concerns in younger patients such as weight gain due to antihistaminergic effects, may even be beneficial for elderly patients often suffering from anorexia and weight loss. In addition, special attention must be paid to frequent medical comorbidities and potential drug–drug interactions.

Because of a reduced hepatic metabolism and renal elimination rate in the elderly, the appropriate dosages are lower than in younger patients (Chiu 1997). The Guidelines of the American Psychiatric Association emphasize that elderly patients typically require a lower dosage than younger patients to reach a particular blood level and tolerate a given serum concentration less well. However, the blood levels at which antidepressant medications are maximally effective appear to be the same as for younger patients (Wilson et al. 2001). Elderly depressed patients are particularly prone to the side effects of antidepressants, particularly cardiovascular side effects and treatment-related cognitive dysfunction (Moskowitz and Burns 1986). For patients with poor health, it is recommended to commence treatment with a low dosage and titrate gradually to the therapeutic dosage range (“start low and go slow”). But this caution can result in underdosing and suboptimal treatment regimes have been reported in up to 45% of elderly patients treated with antidepressants (Wang et al. 2005).

Older patients tend to take longer to recover from depression, recovery may have a later onset and improvement may continue up to 12 weeks, provided that there has been some earlier response. Currently at least 6 weeks of treatment is recommended to evaluate responsiveness (Wilson et al. 2001). After remission, maintenance treatment does not differ from what is recommended for adults in general (see Table 66–2) (Geddes et al. 2003).

ECT has been shown to be very effective. The use of modified ECT (a historical term which refers to the actual standard procedure of electroconvulsive treatment including anesthesia and muscle relaxation), which has fewer cognitive side effects, is now encouraged, especially in patients at particular medical risk for the use of antidepressants (Abrams 2002).

The empirically based psychotherapies, principally CBT and interpersonal psychotherapy (IPT) (Weissman et al. 2000), have demonstrated efficacy largely independent from age (et al. 2006). They may also be of special usefulness as sole treatment in minor depression to avoid the medical risks of pharmacological treatment.

**Gender-Related Differences**

Gender differences in unipolar depression are a consistent finding in several longitudinal and cross-sectional studies (for a review: see Kuehner 2003). The lifetime prevalence shows an unadjusted mean female: male ratio of 2.1 whereas the point prevalence gender ratio is 1.7 (Angst et al. 2002b).

Several differences in comorbidities, symptomatology, and coping style between genders have been described.
Disorders comorbid with depression and more frequent in females include anxiety, somatoform disorders, and eating disorders, especially bulimia, whereas men are more likely to suffer from comorbid alcohol and drug abuse (Marcus et al. 2005). In part, this may also reflect how men and women cope with depression, for example, Angst et al. (200b) found that depressed men were more likely to increase consumption of alcohol whereas women tried to cope through emotional release and religion.

The STAR*D study (Marcus et al. 2005) showed a significantly earlier age of onset of the first major depressive episode in women, and longer current major episodes in women compared to men. In the large Depression Research in European Society (DEPRES) I and II-study, women were significantly more likely to have five or more diagnostic symptoms of depression than men (female: male ratio 1.96) (Angst et al. 2002b).

A few features of depression appear more prevalent in men than in women, for example a tendency to overreact and anger attacks (Winkler et al. 2005).

Explanations for these gender differences are manifold and several factors may contribute, including, genetics, sex hormones, different endocrine stress reactivity, a higher incidence of thyroid axis abnormalities, prior anxiety disorders, personality traits, neuropsychological factors, gender role and psychosocial factors, and life events, for example, childhood sexual abuse (Kuehner 2003). So far, there are no consistent findings for gender differences in heritability (Kendler 1998), but gender-specific genetic polymorphism may play a role in different responsiveness and speed of onset of antidepressant action (Baghai et al. 2004).

Sex hormones may also modulate the manifestation and course of depression, and also treatment response. Specific vulnerabilities and complex interactions between the brain and gonadal hormones do exist (Halbreich and Kahn 2006). Thus, depressive symptomatology in vulnerable women seems to increase when their physiological estradiol levels decrease, for example, perimenstrually, in the postpartum period or during perimenopause. In addition, the efficacy of antidepressants seems to be influenced by estradiol levels (Pinto-Meza et al. 2006). Several, but not all, studies have shown estrogen treatment to be effective in postpartum as well as perimenopausal depression (for review: see Kahn and Halbreich 2005). Estrogens may enhance serotonergic activity and induce a better responsiveness to SSRIs (Stahl 2001). Estradiol may also be involved in the desensitization of the 5HT1A receptor (Carrasco et al. 2004). Other neuroendocrine axes, such as the HPA and thyroid axis, may exhibit subtle differences between genders and thereby influence vulnerability to depression (Kornstein et al. 2002).

The apparently straightforward question of whether gender influences response to different types of antidepressant is complicated by age, menopausal status, and tolerability considerations. There is some evidence that younger women respond preferentially to SSRIs over noradrenaline reuptake inhibitors (TCAs, maprotiline, reboxetine) (Berlanga et al. 2006), respond better to SSRIs than men (Khan et al. 2005) and tolerate TCA less well than men (Baca et al. 2004, Kornstein et al. 2000), but no significant effects of gender were seen in studies comparing SSRIs with clomipramine in inpatients, with the SNRIs venlafaxine, and duloxetine or with bupropion (Anderson et al. 2008, Hildebrandt et al. 2003).

In summary, neither prevalence or symptomatology nor treatment response or consequences of depression are identical in men and women, and a gender-specific psychiatric approach, taking into account gender-specific risk- and influencing factors, including gender roles, is warranted.

### Treatment of Depression During Pregnancy, Postpartum Depression, and Breast-Feeding

The pregnancy and postpartum periods are considered to be relatively high risk times for the development of depressive symptoms or even MDD in women (for review see Cohen et al. 2004). Both acute and prophylactic treatment

of depressive disorders, during pregnancy, require an individual risk/benefit analysis. For mild to moderate depression, psychotherapeutic counseling should be considered first, especially as depression may often be related to the changing role of the young mother. In severe MDD, however, this may not always be sufficient, and antidepressants need to be prescribed. Otherwise, if untreated, impaired feto-placental function, premature delivery, miscarriage, low fetal growth, and other perinatal complications may be the consequence. However, the use of antidepressant drugs in pregnancy might increase the risks of teratogenesis, neonatal toxicity, discontinuation symptoms, and neuropsychological and behavioral impairment (Bellantuono et al. 2006). After birth all available antidepressants are excreted into the milk at a concentration of approximately 1% of the corresponding plasma level (for review: see Burt et al. 2001). There is no ideal solution: the risk of an untreated depressive disorder causing maternal stress influencing also the fetus and birth outcome, and an enhanced risk for suicide, have to be weighed against a possibly enhanced, although rarely proven, risk for fetal malformations, growth impairment, fetal and neonatal toxicity, and behavioral aberrations caused by antidepressant treatments (Wisner et al. 2000).

The evidence for harmful effects of antidepressants is inconsistent. TCAs and fluoxetine or other SSRIs have been considered safe in pregnancy (Wisner et al. 1999). A meta-analysis reported that the use of newer antidepressants such as SSR1, SNRI, NARI, NaSSA, and Dopamine and Noradrenaline Reuptake Inhibitor (DNRI) is not associated with an increased risk of major malformations (Einarson and Einarson 2005), but recent studies observed a potentially increased risk for congenital malformations after paroxetine treatment (Cuzzell 2006). In addition, an arguable case-control study reported an association between the maternal use of SSRIs in late pregnancy and persistent pulmonary hypertension in newborns, probably causing a substantially enhanced infant mortality (Chambers et al. 2006).

For severe MDD, ECT can safely be administered during pregnancy and breast-feeding (Rubheru 2001). Sleep deprivation or bright light therapy might be suitable options for mild to moderate depression.

Cultural Presentation and Ethnic Differences of Depression
The prevalence of depression worldwide varies greatly and appears to be relatively rare outside the western world. An extended WHO household survey using the WHO Composite International Diagnostic Interview of more than 60,000 adults in 14 countries (in North America, South America, Europe, Middle East, Africa, and Asia), gave 12-month prevalence rates of mood disorders ranging from 0.8% (Nigeria) to 9.6% (USA) (Demyttenaere et al. 2004).

A possible explanation for the discrepancy is that most diagnostic criteria for depression and the scales used in developed countries may not be appropriate for assessing functional impairment in rural developing country communities, and that many features of depression, for example, fatigue, could be misinterpreted as signs of HIV infection. But there may be also true differences, including a lower genetic vulnerability, dietary, and other environmental factors, for example, fish intake or sunlight exposure, less exposure to social or occupational stress, or better coping mechanisms. These remain unproven.

Within one country, many of the environmental factors should be equal, and differences in the rate of depression among groups of different ethnicity may be more likely due to biological (genetic) and psychosocial factors. When comparing ethnic groups within the US and controlling for confounding variables such as age, gender, marital, and socioeconomic status (Regier et al. 1993), the prevalence of major depression is similar but outcome varies considerably. As shown in the “Sequenced treatment alternatives to relieve depression” (STAR*D) study, patients of Afro-American or Hispanic origin are at a greater risk of developing chronic depression (Gilmer et al. 2005), but at the same time, they are less likely to receive adequate treatment. Fewer than half of the African Americans (45.0%) and only a quarter (24.3%) of the Caribbean blacks who met DSM-IV-TR MDD criteria received any form of therapy for depression (Williams et al. 2007). More public awareness and lowering thresholds to treatment in minorities is obviously required.

Etiology and Pathophysiology

Neurobiological Factors
Although the anatomical and physiological basis of depression is far from being completely understood, MDD most likely involves the limbic structures (in circuits involving the cingulate-hippocampus-mamillary bodies-anterior thalamus-cingulate), reward circuits (nucleus accumbens, sub-lenticular extended amygdala, amygdala, ventral tegmentum, cingulate, insula, thalamus, parahippocampal gyrus, and prefrontal cortex), hypothalamus, and anterior temporal cortex (Drevets 2000). Both deficiencies of neurotransmitters involved in these circuitries as well as damage to neurons and loss of connectivity, for example, by enduring hypercortisolismia, can underly what manifests clinically as depression.

Monoamine Deficiency Hypothesis

Noradrenaline and Serotonin
Neurochemical dysfunction of central nervous neuromodulatory systems is a widely accepted hypothesis as the pathophysiologic correlate of depression. In 1965, Schildkraut developed the catecholamine/noradrenaline deficiency hypothesis (Schildkraut 1965) and in 1967, Coppen formulated the serotonin deficiency hypothesis (Coppen 1967). The basis of these theories was the discovery of depressiogenic properties of the alkaloid reserpine, a primarily antihypertensive agent, which causes depression due to depletion of monoaminergic synapses (Shore et al. 1955).

Additional support for this theory includes the finding that 3-methoxy-4-hydroxy-phenylglycole in cerebrospinal fluid, blood, and urine of depressed patients (Berman et al. 1999) and diminished concentrations of 3-methoxy-4-hydroxy-phenylglycole in cerebrospinal fluid, blood, and urine of depressed patients (Garlow et al. 1999).

Support for the serotonin deficiency hypothesis is provided by the tryptophan depletion test. The individual is instructed to restrict intake of the amino acid tryptophan.
which is an important precursor in the synthesis of serotonin (Delgado 2000). Although monoamine depletion does not decrease mood in healthy humans (Ruhe et al. 2007), it may reactivate depressive symptoms in remitted patients treated with SSRIs. Further evidence stems from the observation that the concentration of 5-hydroxyindole acetic acid (5-HIAA), which is a main metabolite of serotonin, is reduced in the cerebrospinal fluid of depressed patients in comparison to healthy controls (Cheetham et al. 1991). This deficiency has been associated with aggressive and suicidal behavior in depressed patients (Asberg et al. 1976). The observation that imipramine reduced the transport of noradrenaline and serotonin into rat brain slices in vitro, whereas iproniazid, the first clinically effective MAOI, inhibited the intraneuronal metabolism of biogenic amines, gave further support to the emerging monoamine hypothesis of depression (Ban 2001). But in spite of more than 40 years of research, these findings are able to explain only some, but not all aspects and symptoms of depressive disorders.

Dopamine

It has been postulated that predominantly mesolimbic dopaminergic neurons which connect the ventral tegmen-
tum with the ventral striatum (nucleus accumbens) may play a role in the pathogenesis of depressive disorders. They have a crucial role within the endogenous central nervous reward system, which is important for motivation, reinforcement of behavior, and reward (Berridge et al. 2003). Depressed patients suffering from psychomotor retardation show reduced dopamine turnover, reduced sensitivity of central dopamine receptors, and a diminished intrasynaptic central nervous concentration of dopamine (Dunlop and Nemeroff 2007). Further evidence comprises the dopamine-depleting properties of reserpine (Goodwin et al. 1972) causing depressive syndromes with psychomotor retardation and the high comorbidity of depression with PD which is known to lead to a decline of dopaminergic neurons within the CNS. The efficacy of antidepressants enhancing dopaminergic neurotransmission such as bupropion or amineptine (Papakostas 2006) and the efficacy of dopamine receptor agonists such as bromocriptin, pramipexole, or ropinirole lend further support to this hypothesis (Dunlop and Nemeroff 2007).

Glutamate

In depressed patients, enhanced glutamate concentrations in vivo within the occipital cortex have been shown using MRI spectroscopy (Sanacora et al. 2004) and postmortem in the frontal cortex. Probably due to enhanced glutamater-
gic neurotransmission, a compensatory downregulation of glutamatergic receptors may be responsible for a reduced binding capacity of MK-801, an N-methyl-D-aspartate (NMDA) receptor antagonist (Hashimoto et al. 2007) and of the glycine-binding sites of the NMDA receptor in suicide victims (Nowak et al. 1995). Drugs that target the NMDA receptor have shown antidepressant properties in both clinical and preclinical studies, for example, ketamine (Zarate, Jr. et al. 2006) and riluzole (Sanacora et al. 2007), and the mood stabilizing anticonvulsant lamotrigin, which blocks glutamate release, demonstrated antidepressant properties in bipolar depression (Calabrese et al. 1999) and as augmentative treatment in MDD.

Antidepressant properties in animal models (Robichaud et al. 2001) and in open trials in humans have been postulated for other NMDA antagonists such as MK-801 or amantadine (for review: see Muller and Schwarz 2007), but the cognitive side effects of these agents and their psychotomimetic properties complicate their use, so better tolerated agents would be needed.

Finally, interactions between the central nervous glutamateergic and the serotonergic system and their modulation via the immune system may be of importance (Muller and Schwarz 2007). In addition, the recent finding that genetic variation in a kainic acid-type glutamate receptor is reproducingly associated with response to the antidepressant citalopram, suggests that the glutamate system plays an important role in modulating response to selective SSRIs (Paddock et al. 2007).

\textit{γ-Aminobutyric Acid} (GABA)

A variety of altered functions of the inhibitor neurotransmitter GABA can be demonstrated in depressed patients (for review: see Brambilla et al. 2003). These include reduced concentrations of GABA in the CSF; a decreased number of GABAergic neurons within the orbitofrontal cortex; diminished cortical GABA concentrations in women suffering from postpartal depression; reduced growth-hormone stimulation after treatment with the GABA type B-agonist baclofen; and an imbalance of neuroactive steroids (allosteric modulators of specific neurotransmitter receptors such as GABA type A receptors). Patients suffering from depression may also have an imbalance of GABAergic neuroactive steroids. It has been shown that antidepressants are capable of changing the concentration of neuroactive steroids, which in turn impacts on GABAergic neurotransmission. This mechanism may contribute to their antidepressant action (Rupprecht 2003).

Substance P and Neurokinin Receptors

Substance P is a neuropeptide within the family of tachyki-
inins, which exert their biological effects via G-protein-coupled neurokinin (NK) receptors. It binds selectively to NK1 receptors, which are found within the CNS in regions important for affective behavior and stress reactions (Rigby et al. 2005). NK1-receptor knockout mice show a reduction of anxiety and stress-related behavior (Stout et al. 2001). Elevated serum concentrations of substance P in depressed patients, which can be diminished by antidepressant treatment, have been shown in several studies (Bondy et al. 2003, Lieb et al. 2004). Putative anxiolytic and antidepressant properties of NK1 antagonists have been postulated but a recent meta-analysis of five studies investigating the NK1 antagonist aprepitant failed to confirm antidepressant efficacy (Keller et al. 2006).

Neuroendocrine Hypothesis

HPA-Axis

Both hypo- and hyperthyroidism may influence depressive symptoms. A distinct proportion of depressed patients show diminished tri-iodothyronine (T3) levels (Linnoila et al. 1983). This “low-T3-syndrome” can also be induced by glucocorticoids (Rupprecht et al. 1989). About 25–30% of depressed patients show diminished secretion of thyroid
related not only with the severity of disease, indicated by

stimulating hormone (Loosen and Prange 1982), possibly due to chronic hypothalamic hypersecretion of thyrotropin-
releasing hormone that downregulates its receptors in the
Although changes to the hypothalamic-pituitary-
throid are nonspecifi c and can be shown only in a small
proportion of depressed patients, both thyroxine (T4) and
T3 augmentation of antidepressant treatments has been shown to be effective in treatment-resistant depression.

**Growth Hormone (GH)**
GH stimulation tests have repeatedly shown diminished
secretion in depressed patients (Dinan 1998). In addi-
tion, sleep polysomnography demonstrates reduced slow
wave sleep and a shortened REM latency in depressed
patients. It has been postulated that hypoactivity of the
GH system together with hyperactivity of the HPA axis
may be responsible for this phenomenon (Ehlers et al. 1987). Improved concentration, better memory functions, better mood, and relief of depression have been reported in GH-deficient adults treated with human GH (Mahajan et al. 2004).

**Gonadal Steroids**
Estrogen may strongly infl uence the susceptibility for
depressive disorders with the risk being higher in women
during their reproductive phase which is characterized by
cyclic fl uctuations of gonadal steroid concentrations. The
rapid decline of gonadal steroids in the postpartum period
seems to be a risk factor for the development of depressive
disorders (Payne 2003). Finally, estrogen concentrations are
diminished in depressed female patients in comparison to
healthy controls of the same age (Young et al. 2000).

Hormone replacement therapy in postmenopausal
women showed antidepressant effects in some studies (see
Section, “Gender-Related Differences”). Preclinical investi-
gations indicate estrogen is capable of enhancing serotonin-
gic neurotransmission (Amin et al. 2005) which may explain
the reported higher responsiveness to SSRI treatment in
women (Kornstein et al. 2000).

In depressed men, diminished testosterone levels have
been found in comparison to healthy probands (Schweiger et al. 1999) and the incidence of depressive disorders correlates negatively with testosterone levels in elderly men (Shores et al. 2004). Testosterone replacement therapy shows anti-
depressant effects, but its clinical use is limited due to the

**HPA-Axis**
For a long time, dysregulation of the HPA system has been
known as one of the major neuroendocrine abnormali-
ties in MDD. This includes raised levels of corticotropin
releasing factor (CRF) (Nemeroff et al. 1984), adenocor-
ticotropic hormone, and cortisol (Linkowski et al. 1987)
during depressive episodes, which normalize after clinical
remission. Enhanced HPA activity during the fi rst weeks
of antidepressant pharmacotherapy seems to be associated
with lower rates of early treatment response (Hatzinger et al. 2002). Furthermore, persisting cortisol hyperscretion indicates a higher risk for the recurrence of depression, even if clinical remission has been achieved (Zobel et al. 1999). Long-term deterioration of the HPA system is highly cor-
related not only with the severity of disease, indicated by
higher scores on measures of depression, but also with a
greater number of episodes (Hatzinger et al. 2002).

Both in molecular investigations and animal studies, it has been shown that TCAs, MAOI, and some SSRIs modulate the regulation of the HPA system by enhancement of the expression of glucocorticoid receptors, thereby improv-
ing the feedback mechanism of the HPA system (Barden et al. 1995, Nemeroff et al. 2004).

Today, the HPA axis has become an important target for
the development of new antidepressants. One approach
has involved antagonists of CRF 1 receptors. Clinical stud-
ies have shown that the concentration of CRF is increased
in the CSF of both suicide victims and depressed patients
(Nemeroff 1996a). However, so far CRF antagonists have
not shown efficacy in the treatment of depression in RCTs.
More success has been reported in the development of glu-
cocorticoid type-2 receptor antagonists. This approach was
based on the observation that hypersecretion of cortisol is
a frequent occurrence in patients with chronic depression
in which melancholic features are prominent. There is pre-
liminary clinical evidence that novel glucocorticoid receptor
antagonists may be benefi cial in such subgroups of depressed
patients (Gallagher and Young 2006). For psychotic depres-
sion, there is preliminary evidence that antiprogesterone and
glucocorticoid receptor antagonist mifepristone is effec-
tive both on mood symptoms and, even more, on psychotic
features; however, these studies are not conclusive (Carroll
and Rubin 2007). Finally, the steroid synthesis inhibitor
methyrapone has shown acceleration of response to antide-
pressant treatment in one RCT (Jahn et al. 2004), but repli-
cation studies are still needed.

**Disturbances of Sleep and Biological Rhythms**
Most patients with depression experience signifi cant
changes in sleep such as insomnia, hypersomnia, or exces-
sive drowsiness which contribute greatly to the morbidi-
ty of the disorder, including reduced quality of life and
diminished functioning (Krystal et al. 2007). Persistent
sleep disturbance is a predictor of relapse and recur-
rence of depression. Ironically, sleep deprivation has been
reported to reduce depressed mood, at least transiently. The
reasons for this fi nding are not clear.

Sleep can be viewed as a part of the normal oscillat-
ing 24 hour biological cycle, or circadian rhythm. A variety
of biological processes are infl uenced by circadian rhythms,
including body temperature and secretion of various hor-
mones, such as melatonin, growth hormone, prolactin, and
cortisol. This rhythm is believed to be driven by several
innate biological clocks, but is also infl uenced by the pro-
gression of the seasons and the changing photoperiod.

Sleep disturbances in depression can be divided into
subjective complaints such as insomnia, hypersomnia, or
excessive sleepiness and objective fi ndings documented using
polysomnography. Insomnia is the most common complaint
and can include diffi culty falling or staying asleep as well
as early morning awakening, the classic fi nding in depres-
sion. Patients who experience insomnia oft en have daytime
sleepiness. However, up to 20% of depressed patients report
hypersomnia, especially those patients with atypical features.
Many patients also report not feeling rested (nonrestorative
sleep), decreased total sleep, and disturbing dreams (Krystal
et al. 2007).
Abnormal polysomnography findings are common (although not universal) in depression. Total sleep time as well as the continuity of sleep is often decreased. Sleep is fragmented with frequent awakenings. Sleep efficiency (time actually asleep while in bed) is also reduced. Typically, there is a reduction in total duration as well as the percentage of nonrapid eye movement sleep (NREM). The duration of NREM prior to the first rapid eye movement sleep (REM) period, known as REM latency, is often decreased in depression. It is not clear whether depression-related sleep disturbances are trait markers for vulnerability to depression or are limited to periods of illness. Some evidence suggests that some sleep EEG findings may precede the onset of clinical depression. Indeed, some authors theorize that circadian rhythm disturbances are a core feature of affective disorders. These abnormalities in sleep and circadian rhythms are among the most consistent findings in biological psychiatry and successful treatment of depression often results in improved sleep. However, many other psychiatric and medical conditions which may be comorbid with depression, as well as alcohol, substance abuse, and medications, also affect sleep (Krystal et al. 2007, Thase 2007).

In addition to circadian rhythms, biological rhythms exert their effects over shorter and longer time lines. Ultradian rhythms oscillate more than once in a 24 hour period, while infradian rhythms operate over a much longer time period. These infradian cycles may entrain to seasonal changes in the photoperiod and it has been postulated that disturbances in infradian rhythms play a role in SADs (including winter depression). Light therapy (phototherapy) uses a full spectrum lamp to mimic the effects of sun exposure. It is usually given in the morning and believed to exert its therapeutic effect by resetting the biological clock (Terman 2007).

Genetic Factors
Recent family studies have reported an approximately 3-fold increased risk for MDD in the first-degree relatives (parents, siblings, offspring) of individuals with MDD versus the general population, although there is some variation, due most likely to differences in diagnostic and sampling criteria (Sullivan et al. 2000). However, this finding is not specific: first-degree relatives of MDD patients also show a higher risk for developing anxiety disorders (Camp et al. 2005), eating disorders (Mangweth et al. 2003), substance abuse (Preisig et al. 2001), and other affective spectrum disorders (Hudson et al. 2003). Family studies alone do not allow one to distinguish the effects of genetic factors versus family environment. Complex disorders, of which MDD is a good example, are likely to involve a relatively large number of individual genes, none of which may themselves have a major impact on risk, as well as interactions with environmental factors.

Research has tended to focus on genes encoding neurotransmitter receptors and on the enzymes involved in monoaminergic transmission. The studies have used only small sample sizes and found only minor genetic effects, most of which could not be replicated. Nevertheless, meta-analysis has identified several genetic variants of candidate genes.

Several studies concentrated on promoter polymorphism in the serotonin transporter gene, which has a short allele that shows an association with depression and anxiety (Lesch et al. 1996), as well as enhanced susceptibility to stressful life events (Caspi et al. 2003). However, other investigations were not able to replicate this finding (Minov et al. 2001, Serretti et al. 1999). Polymorphisms of other receptors and enzymes of the biogenic amines have also been investigated. These include the tyrosine and tryptophan hydroxylase genes, the catechol-O-methyl transferase gene as well as genes for the serotonin and dopamine receptors (Kato 2001). But again, these studies have yielded inconclusive or negative results.

Functional polymorphisms in the angiotensin converting enzyme gene seem to influence the risk for developing depressive disorders (Arinami et al. 1996, Baghai et al. 2006a), HPA axis activity (Baghai et al. 2002), and the clinical effectiveness of antidepressant therapies (Bondy et al. 2005). Additionally, the glucocorticoid receptor-regulating co-chaperone FKBP5 has been shown to influence both the susceptibility for depression and response to antidepressant treatment (Binder et al. 2004).

The conventional view that unipolar depression is evoked by the same genes irrespective of the age of onset of the disorder has been challenged by studies on late-onset depression. Hickie et al. (Hickie et al. 2001) demonstrated that late-onset depression is associated with a mutation in the methylene tetrahydrofolate reductase gene that encodes an important cofactor in monoamine biosynthesis; this mutation was not observed in patients with early-onset depression. It appears that the same mutation predisposes the patient to cerebrovascular disease and is associated with increased plasma homocysteine and folate deficiencies that frequently occur in late-onset depression.

There are only a few small studies published in which pharmacogenetics has been used to predict therapeutic response in individual patients. These studies have investigated variations in the genes for serotonin receptors and the serotonin transporter and their associations with a poor response to treatment with SSRI antidepressants (Joyce et al. 2003, Zanardi et al. 2001). Again, other investigators have been unable to replicate the observations (Kim et al. 2000). The STAR*D study found that homozygote carriers of the treatment-response-associated marker alleles of both the GRIK4 and HTR2A genes were 23% less likely to experience nonresponse to treatment with citalopram relative to participants who did not carry any of these marker alleles, suggesting the importance of interactions between serotoninergic and glutamatergic transmission (Paddock et al. 2007). A more extensive update can be found in published reviews on pharmacogenetics and pharmacogenomics (Serretti et al. 2005).

Neurotrophic Factors
A continuous accrualment of neurons (neurogenesis) in the gyrus dentatus, a region within the hippocampus which is important for mood regulation, has been demonstrated (Eriksson et al. 1998). The neurotrophin hypothesis of depression and antidepressant effectiveness now postulates a depletion of neurotrophic factors such as brain-derived neurotrophic factor during depression, resulting in diminished neurogenesis and damage of predominantly hippocampal neurons, which can be counteracted by antidepressant treatments (Duman 2002). It has also been postulated that
stress and hypercortisolism in untreated depression results in hippocampal atrophy, including reduced synaptic plasticity due to a reduction in the length and numbers of dendritic branching (Sapolsky 2000). Neuroimaging supports this postulated enhanced neuronal degeneration within these regions in depressed patients (Frodl et al. 2002), and in healthy controls an association between hippocampal atrophy and cortisol levels has been reported (Lupien et al. 1998).

Chronic antidepressant treatment results in an enhanced expression of neurotrophic factors (Thome et al. 2002) and in an augmented neurogenesis within hippocampal regions (Malberg et al. 2000). This may explain the latency of several weeks before sufficient antidepressant action is observed in the treatment of MDD. In animal models nonpharmacological antidepressant treatment options such as sleep deprivation (Hairston et al. 2004), ECT (Stewart and Reid 1993), and repetitive transcranial magnetic stimulation (Muller et al. 2000) increased concentrations of brain-derived neurotrophic factor, whereas in depressed patients after ECT inconsistent results have been reported. Finally, effects on neurogenesis can not be the sole mechanism of antidepressants as their effectiveness is not always linked to action on neurotrophic factors (Coppell et al. 2003).

Animal Models of Depression

There is presently great concern about the relevance and predictive validity of animal models of behavioral disorders (Wisnisky and Brady 2005), partially caused by the discrepancy between positive outcomes of candidate drugs in animal models followed by apparent lack of efficacy in humans. This raises the question whether an observed behavior in animals really resembles, at least in part, a depressive syndrome in humans. Depression presents as a heterogeneous entity made up of a variety of emotional, behavioral, and cognitive elements, and each component of the syndrome may involve different neurobiological substrates. It must be kept in mind that DSM-IV-TR and other classification systems simply provide diagnostic criteria based on changes in behavior and placing labels on the abnormal behaviors does not imply etiology.

When using animal models, we have to be aware that they can only model a very specific and limited facet of either behavior or neurochemical changes involved in depression. Animal models are used (1) to reproduce aspects of the behavioral disorder that can be studied, (2) as a test bed for discovering novel pharmaceuticals that may treat the disorder, and (3) as procedures through which new molecular targets can be identified for subsequent drug discovery and development.

Antagonism of the pharmacological effects of reserpine was the first model of abnormal monoaminergic function in depression where antidepressants were differentiated from other psychoactive drugs (Askew 1963). Reserpine nonselectively depletes synaptic stores of the monoamines noradrenaline, dopamine, and seratonin, and induces a syndrome of locomotor hypomotility and reduced body temperature. These behavioral symptoms can be reversed by different TCAs and MAOIs.

Similarly, hypothermia induced by high doses of the dopamine agonist apomorphine is reversed by antidepressant compounds (Puech et al. 1981), likely due to action on dopaminergic receptors on noradrenergic terminals, preventing noradrenaline release. Neither the reserpine nor amphetamine model attempts to mimic any of the behavioral symptoms of depression per se, they simply reveal activity of compounds in elevating synaptic concentrations of monoamines.

Neurochemical models were used to investigate receptors involved in the etiology of depression and thought to be a marker of the disorder. Changes in β-adrenergic receptor number and sensitivity, for example, have been associated with depression and suicide (Leonard 2000) and chronic treatment with TCAs could reduce the number of β-adrenergic receptors (McArthur and Borsini 2006).

An alternative approach in animal models was to induce behavioral changes not by drugs, but by negative environmental factors or stress, and then test the capability of potential antidepressants to prevent or reverse these behaviors. It is a very strong assumption in most models that depression can be viewed as a maladaptive response to stress (Wong and Licinio 2001).

The separation of infant monkeys from their mothers was one of the earliest models of the effects of social and environmental stress. Infant monkeys react to this separation initially by protesting and finally with behaviors resembling despair. Similar effects are observed following maternal separation in other animal species.

Chronic stress and depression in humans are often characterized by HPA axis dysfunction. Thus, stress-induced HPA dysfunction in animals may serve as a test bed for observing both subsequent anatomical and functional changes and their response to antidepressant treatment. Even brief periods of separation of a rat pup from its mother can induce endocrine responses related to stress such as increased corticotrophin-releasing factor and decreased glucocorticoids in various brain areas (Francis et al. 1999a). Rats that have experienced prolonged separation as pups show signs of HPA hyperactivation including decreased glucocorticoid receptor activation in the hippocampus, hypothalamus, and frontal cortex, and reduced negative feedback sensitivity. Similar to depressed patients, these animals show an early release from dexamethasone-induced suppression of basal adrenocorticotropic hormone (Nemeroff 1996b). Disruption of normal maternal care can not only cause sustained hyperactivity of the HPA system in response to adulthood stressors but also lead to increased anxiety- and depression-related behaviors in the adult offspring (Francis et al. 1999b).

Stress can also be induced by competition within a social milieu. A model of depression based on social hierarchy and subordination was proposed by Malatynska and Kostowski (1984). Pair-housed rats are forced to eat within a limited time, which means that the dominant member of the pair alone managed to eat sufficient food. Repeated treatment with an antidepressant helps the submissive animal to become more assertive and compete longer for food. Stress induced in socially housed rats alters neuroendocrine variables: subordinate animals showed not only increased defensiveness, increased ethanol consumption, and shorter lifespan than dominant rats but also had significantly elevated corticosterone levels and increased 5-HIAA/5-HT ratios, indicating a whole range of changes consistent with a depression-like profile (Blanchard et al. 1993). Interestingly, social hierarchy models can also be fitted in a way that they...
may resemble manic behaviors (Malatynska and Knapp 2005).

Another example of an acute stress paradigm leading to lasting behavioral changes is the learned helplessness model which was proposed and developed during the 1960–1970s. A presumed state of depression is induced in animals by exposing them to an aversive stimulus like a weak electric shock under circumstances in which they cannot control or predict the onset or duration of the stimulus. Rats subjected to this procedure show long-lasting deficits in the motivation and ability to escape in subsequent trials where escape is possible, reduced locomotor activation and grooming, increased passivity, decreased appetite and decreased interest in sexual activity in a manner reminiscent of the anhedonic syndrome of depression in humans (Willner 1986). Helpless rats also develop alterations in sleep–wake patterns with modifications of the latency and amount of REM classically observed in depressed humans (Adrien et al. 1991). Pharmacological treatment with TCAs reduces these behavioral changes (McArthur and Borsini 2006). Nevertheless, the learned helplessness paradigm has shortcomings. Antidepressants work nonspecifically in a wide range of stress-related disorders and depression, thus, learned helplessness may be a better model of posttraumatic stress disorder and other conditions in which stress is a clear etiological factor than it is of depression.

The forced swimming test, also called behavioral despair, was first proposed as a simpler variation of the learned helplessness test, and is probably the most widely used screening test of antidepressant potential of novel compounds. Animals are forced to swim in a confined space. They become immobile following a phase of extensive swimming and climbing. Antidepressants from all classes reduce the immobility time when the rat is replaced in the water cylinder 24 h following the initial experience. Interestingly, different classes of medication may change different behaviors: SSRIs seem to prolong swimming time, whereas NARIs seem to increase climbing behavior (Nestler et al. 2002).

A variant of the forced swim test, used in mice, is the tail suspension test. Here, mice are suspended by their tails and the time it takes an animal to become immobile (to hang passively upside down) is measured. The major advantage of the forced swim or tail suspension test is its relatively high throughput and ease of use (Nestler et al. 2002). The test also provides a useful model in which to study the neurobiological and genetic mechanisms underlying stress and antidepressant responses (Lucki et al. 2001, Porstl 2000).

One of the defining characteristics of MDD is, however, a persistence of depressed mood over a number of weeks. In addition, acute stress models do not allow for comparing the onset of action of compounds. A rapidly acting antidepressant would offer considerable advantages over existing therapies. Therefore, tests have been developed that require a prolonged period of treatment for the effects of antidepressant drugs to be observed. The most widely applied test is the olfactory bulbectomy model (Cairncross et al. 1977). Pheromone detection is very important in the psychosocial milieu of the rat. The olfactory bulbs receive incoming chemosensory information and relay this to limbic structures via an extensive network of neuronal connections. Bilateral aspiration of the olfactory bulbs thus deprives rats of this vital mediator with the external environment and results in dysregulation of the limbic–hypothalamic axis, increased sensitivity to stress, alterations in immune function, abnormal sleep patterns, agitation, weight loss, and changes in hedonic behavior (Song et al. 2005). The most notably behavioral change following olfactory bulbectomy is increased exploration and hyperactivity in an open field test that can be attenuated by chronic administration of antidepressants of various classes (Kelly et al. 1997). On a biochemical level, olfactory bulbectomy reduces concentrations and turnover of noradrenaline and serotonin in cortical forebrain regions and concentrations of noradrenaline in the frontal cortex. However, it may simply be that the chronic sensory deprivation caused by the destruction of the primary mode for receiving external sensory information constitutes a chronic stressor of high intensity.

**Psychological Factors**

Depression is a multifactorial clinical phenomenon. In any case of depression, biological, environmental, and psychological factors may interact to varying degrees. Significant theoretical approaches to the psychology of depression to be considered include cognitive behavioral, interpersonal, social rhythm theory, and psychodynamic. The strength of these approaches has generally been in their utility rather than the power of their etiological theories, which have proven difficult to verify empirically.

Depression may be triggered by stressful life experiences in susceptible persons, but not everyone becomes depressed under similar stressful circumstances. The intensity and duration of the stressors, personality attributes, coping skills, and previous life experiences play a significant role in each individual’s vulnerability to depression. Early life experiences shape how individuals experience the world and their place in it, including subsequent stressful life events. The availability and nature of a social support network is also a crucial variable. Different individuals may assign widely divergent meanings to similar stressful experiences, leading to very different affective and behavioral responses. This is why understanding the relationship between stressful life experiences and depression is not simple. Even seemingly advantageous life events, such as marriage can produce stress. Certain personality styles involving low self-esteem or pessimism may contribute to a difficulty in coping with change.

**Cognitive Theory**

The cognitive or CBT approach to depression was originally developed by Beck (see Beck et al. 1979) and emphasizes a set of dysfunctional cognitions which are believed to contribute to depressive symptoms. From this perspective, cognitive distortions cause and maintain depression. However, the origins of cognitive distortions are not made explicit in CBT theory, which emphasizes a “here and now,” immediate approach to understanding and treating depression. These cognitive distortions are believed to be relatively stable but dormant in asymptomatic individuals, apparently becoming more significant after a stressful life event serves as a trigger. Cognitive distortions are present moment to moment in the form of transient “negative automatic thoughts,” which form a constant background of depressogenic thoughts in response to external events as well as internal experiences such as memories. These thoughts derive some of their power to influence mood through their repetitive nature, and tend
to remain unexamined unless made explicit through therapy. They typically exemplify certain characteristic types of cognitive distortions such as dichotomous (“black and white”) thinking, overgeneralization, and personalization. They are not considered to be unconscious, as the individual is capable of recognizing them through introspection and self-examination. In addition to these transient phenomena, more stable, persistent, and deep seated ideas about one’s self and the world known as “schemas” are important in cognitive theory. Schemas which contribute to depression tend to be somewhat inflexible, known in CBT terminology as “global and invariant.” Beck also described a “negative cognitive triad” involving a negative view of one’s self, one’s world, and the future. Beck envisioned an interplay between cognition and behavior. Depressed patients respond to negative beliefs about themselves by developing self-defeating behavioral patterns, reducing opportunities to experience pleasurable or rewarding experiences.

Cognitive theory also reflects influences by learned helplessness models and hopelessness theory (Abramson et al. 1989, Seligman 1975). In hopelessness theory, “depressogenic attributional style” leads individuals to regard stressful events as permanent rather than temporary, and affecting most of one’s life rather than being limited to specific areas. These attributional styles contribute to personal, internal rather than external explanations of depressive experiences.

Interpersonal Theory
IPT was developed by Klerman and others (Klerman et al. 1984) and has played an important role in modern psychotherapy of depression; however, it does not present a thorough psychology of the etiology of depression. IPT focuses on difficulties in current interpersonal functioning. It involves a formal diagnostic assessment, inventory of important current and past relationships, and definition of the current problem area. In IPT, depression is held to relate to one or more of four functional areas: grief, interpersonal role disputes, role transitions, and interpersonal deficits. In IPT, the reciprocal relationship between one’s mood and interpersonal events is explored. Stressful life events may overwhelm coping ability and produce a depressed mood, which then contributes to ongoing interpersonal difficulties. Once this relationship is identified, modifying it becomes the focus of treatment.

The relationship between psychological well being and one’s interpersonal environment has long been a focus in psychiatry. Authors including Adolf Meyer, Frieda Fromm-Reichmann, and Harry Stack Sullivan emphasized adaptation to the social environment in understanding and treating psychiatric disorders, while Bowlby (1980) and others emphasized social attachment. IPT developed through an appreciation of these earlier thinkers. Numerous studies have shown a relationship between stressful life events (most of which have an interpersonal element) and depressed mood.

Social Rhythm Theory
An attempt at integration of biological and psychosocial theories of depression has focused on the disruption of biological rhythms associated with psychosocial stressors. The loss of “social zeitgebers” (persons, social demands, or tasks which set the biological clock) has been proposed as a link between biological and psychosocial formulations (Ehlers et al. 1988). The loss of social rhythms is held to result in instability in biological rhythms, triggering a depressive episode in a person vulnerable to depression. The social zeitgebers theory suggests that external factors such as social relationships, interpersonal continuity, and work tasks entrain internal biological rhythms. Disruptions of these social rhythms due to loss of relationships interfere with biological rhythms that maintain homeostasis. This disruption leads to changes in neurobiological process including alterations in neurotransmitter functions, neuroendocrine regulation, and neurophysiologic control of sleep/wake cycle and other normal circadian oscillations.

Psychodynamic Theories of Depression
Psychoanalytic thinking has explored depression since the early days of Freud’s original work. Freud (1917) was interested in the distinction between normal grief and clinical depression. In his “Mourning and Melancholia,” he suggested that depression involved a process of “turning aggression inward.” This situation might arise when a close relationship ends through death, illness, conscious decision, or accident. The psychological process of grief, according to Freud, involves withdrawing the emotional attachment felt for the person no longer present. Sometimes, these emotions are ambivalent mixtures of loving and angry or hateful feelings. In such cases, the individual may be unable to resolve the aggressive feelings toward the lost loved one. Freud believed that such feelings have to be resolved, and that resolution in these cases involves the defense of introjection, a turning of the negative feelings inward, against the self. Clinically, this unconscious process would contribute to the guilt, self-criticism, and suicidal ideas which frequently complicate depression.

Later psychoanalytic theorists developed other views of depression. For example, Self Psychology, developed in the 1970s and 1980s, influenced by the work of the psychoanalyst Heinz Kohut (1971), emphasized the importance of maintaining psychological equilibrium. This equilibrium relies on a combination of regulatory capacities within the individual and resulting from important relationships. Kohut used the term “cohesive self” to describe the state in which adequate self awareness, self esteem, self regulation, and interpersonal awareness exist to allow the individual to function in an acceptable way. In this view, the loss of an important relationship with another person can produce a state of self fragmentation, leading to psychological symptoms such as depression. Treatment aims to reestablish a supportive environment, allowing the return of interpersonal and internal equilibrium. Also, a loss or blow to the individual’s identity or sense of self may produce a narcissistic wound or injury. For instance, the loss of a job or significant relationship may play this role. The fragmentation of self in such a case may also contribute to depression. Treatment in these cases must involve reestablishment of one’s sense of self, or even development of a new sense of self (Tasman, personal communication 2007).

Social/Environmental Factors
As summarized by McLean and Link (1994), the two major conceptualizations of how life events affect mental health
are: (1) life events as disruptive experiences that necessitate changes and readjustment and (2) life events as meaningful experiences that arouse negative emotions.

A wide range of environmental adversities such as job loss, marital difficulties, major health problems, and loss of close personal relationships are associated with a substantial increase in risk for the onset of MDD (Kessler 1997). In childhood, a range of problems including physical and sexual abuse, poor parent-child relationships, and parental discord and divorce leave biological scars such as altered HPA axis function and increase the risk for MDD both in adolescence and later in life (Heim et al. 2001).

In the elderly, loss of loved ones constitutes a strong risk factor for depression following grief. Among longitudinal studies of population-based samples using diagnostic criteria, the risk of depression associated with the death of one’s spouse is estimated as 24.3 during the first year, 9.0 during the first 2 years, and 3.1 during the first 3 years (Bruce 2002).

Social and environmental factors may have different effects depending on gender. In a large population–based sample, Kendler and colleagues (Kendler et al. 2001) found that women consistently reported higher exposure to housing problems, loss of confidant, crises and problems getting along with individuals in their proximal network, and illness of individuals in their distal network, whereas men consistently reported higher rates of other stressful life events, such as job loss, legal problems, robbery, and work problems. Consistent sex differences in the sensitivity to stressful life events were seen for only three categories: men were more sensitive to the effect of divorce or separation and work problems, and women were more sensitive to the impact of problems getting along with individuals in their proximal network.

In recurrent depression, social stressors and negative environmental factors may play a more pronounced role in the onset of early episodes, but may lose importance during the course of illness. Kendler and colleagues (Kendler et al. 2000) concluded from their study in the same sample of depressed women that the association between previous number of depressive episodes and the pathogenic impact of stressful life events on major depression is likely causal and bidirectional. In patients with frequent relapses, the association between stressful life event exposure and risk of major depression progressively declines up to the ninth episode, but is then largely unchanged with further episodes. These results are consistent with the kindling hypothesis (Weiss and Post 1998), but suggest a threshold at which the brain is no longer additionally sensitized to the depressive state.

**Treatment**

**Access to Mental Health Services**

Ideally, patients and caregivers should have unrestricted access to mental health and complementary services when needed. According to WHO, however, fewer than 25% (in some countries even less than 10%) of depressed patients receive at least adequate minimal care. The reason is not always a lack of resources, but, other factors, for example, stigma, no insurance coverage or fear of losing one’s job when missing time at work, may also create barriers to effective care. Even in highly industrialized countries, there is a large gap between the relatively high prevalence of depressive disorders and the delayed and relatively infrequent use of antidepressant treatments (Henkel et al. 2005), and reasons may include barriers to access mental health providers or underdiagnosis of depression and inadequate treatment.

**Treatment Goals: Response, Remission, and Recovery**

Clinical trials focus on symptomatic relief measured by specific scales, for example, the Hamilton Depression Rating Scale (HDRS) (Hamilton 1967) or Montgomery Asberg Depression Rating Scale (MADRS) (Montgomery and Asberg 1979), and define response and remission in relation to these scores. The traditional definition of response in RCTs of antidepressants is a 50% improvement compared to baseline score. Remission is defined as the absence of depressive symptoms and a full return of functioning. Most RCTs use an absolute rating scale threshold to define remission, for example, HAM-D score ≤7. When comparing across studies, however, effect sizes expressed as NNT may provide a better estimate of how effective a medication really is.

The goals of clinical management of MDD can be divided into acute, intermediate and long-term, corresponding to the different phases of treatment, namely acute, continuation and maintenance (prophylactic) treatment (Kupfer 2005) (see Figure 66–1). The ultimate goal of acute treatment is to achieve remission, meaning not only being asymptomatic (in the sense of not meeting the criteria for diagnosis of the disorder and having no or only minimal

residual symptoms), but also showing improvement in psychosocial and occupational functioning. From the patient’s perspective, remission means the presence of features of positive mental health such as optimism and self-confidence, and a return to one’s usual, normal self (Zimmerman et al. 2006). The intermediate goal of treatment is stabilization and prevention of a relapse, elimination of subsyndromal symptoms, and restoration of the prior level of functioning. The long-term goal is full recovery (Rush et al. 2006a), to prevent further episodes, maintain functioning, and ensure a satisfactory quality of life. In the following, the different stages of therapy will be elaborated, focussing on the pharmacological treatment.

**Acute Treatment**

At least in severe depression and depression previously unresponsive to psychotherapy alone, initiation of antidepressant treatment is a regular part of the overall treatment plan. If not already ongoing, this treatment plan should also include psychotherapy, psychoeducation, and psychosocial support. The choice of medication depends on several factors including proven efficacy, tolerability and safety, previous experience, and preference of the patient.

Titrating medication usually starts with the lowest effective dose, derived from clinical studies, to ensure good tolerability. If side effects do not occur or fade within a few days, stepwise dosage increases up to the usual standard dose as recommended by the manufacturer (see Table 66–5) can be made until relief from depressive symptoms begins. Independent of the chosen drug, a delay of several weeks may occur until sufficient antidepressant effects can be observed. When switching from one medication to another, overlapping tapering is recommended unless a specific medication, for example, an irreversible MAO inhibitor or fluoxetine, demands a washout-phase (Larsen 1988); in this case, a washout-period of at least 2 weeks (up to 5 weeks, in case of a switch from fluoxetine to irreversible MAOIs) must be observed, especially when treatment with another serotonergic-acting medication is planned; otherwise, a potentially lethal serotonin syndrome may very rarely occur (Boyer et al. 2005). Between 1989 and 1999, 23 deaths caused by a serotonin syndrome were reported in the literature (Gillman 1999). A serotonin syndrome is not specific for SSRIs, but may also happen with other serotonergic-acting substances, for example, venlafaxine in combination with MAOIs (Phillips and Ringo 1995). When switching to reversible MAO inhibitors, for example, moclobemide, a few (2–3) days of pausing medication appear to be enough (Dingemanse et al. 1998). For further details about MAOI tolerability see Section, “MAOI”.

Expectations about the potential efficacy of a given treatment are not uniform across guidelines. It has been estimated that antidepressants currently in use achieve treatment response rates of 50–75% in moderately to severely depressed patients, which means that despite sufficient dosage up to half of patients do not respond sufficiently to the initial treatment choice. Concurrent pain and somatization indicate a longer time course until remission is achieved; especially the presence of bodily pain predicts difficulties in treating depression. These patients may require a more intense treatment right from the start, for example, the use of dual mechanism antidepressants that also address pain and thus increase the patient’s chances of achieving remission (Karp et al. 2005).

The decision concerning whether a response is sufficient can be made clinically or, especially in research settings, be guided by the administration of established rating scales. Nonresponse is usually defined as a less than 25% decrease in baseline symptom severity, partial response as a 26–49% decrease in baseline symptom severity, and response as a greater than 50% decrease in baseline symptom severity (Bauer et al. 2002b). In case of nonresponse after 4 weeks of treatment, a switch of medication is usually recommended. Patients with a partial response after 6–8 weeks should receive a dose escalation, followed by augmentation or switching strategies (Hirschfeld et al. 2002, Quitkin et al. 2005). Recent results of the STAR*D study favor early augmentation, as the likelihood of response to monotherapy steadily declines with each medication switch (Rush 2007). However, there is reasonable evidence that especially in older patients it may take longer to achieve full response to antidepressant medication (up to 12 weeks) (Furukawa et al. 2000).

To bridge the time period until onset of symptomatic improvement and also for the acute relief of distressing symptoms, for example, agitation and sleep disturbances, short-term addition of benzodiazepines could be considered, as these may accelerate the response. A meta-analysis by Furukawa (Furukawa et al. 2001) showed that depressed patients receiving combination therapy were more likely to show a greater than 50% reduction from their baseline depressive severity than patients on antidepressant monotherapy (1.63 times at 1 week, falling to 1.06 times at 6–8 weeks). When benzodiazepines are given, the physician should check on a regular basis whether they are still needed, to prevent the risk of addiction (Clark et al. 2004). Additional early augmentation therapies such as sleep deprivation or light therapy may be considered, especially when the patient has been previously responsive to these modalities.

**The Role of Therapeutic Drug Monitoring**

To establish true refractoriness or to check whether the previous treatment has been appropriate as far as dosage is concerned, therapeutic drug monitoring may be helpful. Serum levels should be measured under steady-state conditions (at least 5 half-lives, in most drugs after 1 week after dosage change) and at the time of minimal drug concentration (trough level). Therapeutic drug monitoring is based on the hypothesis that there is a well defined relationship between the drug plasma concentration and its clinical effects (therapeutic effects, adverse effects, and toxicity). This hypothesis is generally well accepted for lithium and for the TCAs nortriptyline, amitriptyline, desipramine, and imipramine (Baumann et al. 2005). However, results are inconsistent for other TCAs, SSRIs, and other more recently introduced antidepressants (Corruble and Guelfi 2000). Several factors may interfere with antidepressant serum concentrations, including absorption and excretion kinetics of the drug, bioavailability and binding properties to plasma proteins. In combination treatment regimes, various pharmacokinetic interactions between antidepressants and other medications may occur due to their common metabolism by cytochrome P-450 (CYP) enzyme isoforms and/or enzyme inhibition. Genetic polymorphisms of CYP2D6 and CYP2D19 are of high clinical relevance for antidepressants which are
substrates of these enzymes, including TCAs, some SSRIs, venlafaxine, and mirtazapine. About 5–8% of the Caucasian population are considered as poor metabolizers and 1–7% as ultra-rapid metabolizers (Baumann et al. 2005); the former leads to increased serum levels and the latter to insufficient serum concentrations. In Asian populations, the poor metabolizer type may be less frequent (about 1% in Thai, Chinese, and Japanese populations, and up to 4.8% in Indians (Kitada 2003)).

Concomitant medication metabolized by the same enzymes influences the metabolic rate of other substances. For example, some SSRIs inhibit CYP2D6, especially fluoxetine and paroxetine, but also bupropion, with a consequent increase in serum levels of other substrates, for example, antiarrhythmics, beta-receptor antagonists such as propanolol or metoprolol, and opioids, for example, codeine. Other antidepressants, including imipramine, nefazodone, venlafaxine, and reboxetine, are metabolized by the CYP3A4 pathway, with some showing potent inhibition of this enzyme, for example norfluoxetine, the metabolite of fluoxetine and fluvoxamine (Baumann et al. 2005).

Owing to the costs of therapeutic drug monitoring (measuring plasma levels for a single psychoactive drug and its metabolites costs between $25 and $100), it should not be performed routinely, but only in cases with established serum concentration effectiveness/side effect relations and in conjunction with a clinical question, for example, insufficient treatment response, side effects due to overdosing.

Continuation and Maintenance Treatment

General Principles of Maintenance Treatment
The ultimate goal in any psychiatric disorder is to prevent recurrence of acute symptomatology and improve functionality and quality of life in patients.

Prophylactic treatment of unipolar depression is not restricted to pharmacotherapy. Psychotherapy, especially IPT and CBT, should be included in the overall treatment portfolio. Maintaining a good doctor-patient relationship, monitoring adherence and psychoeducation are important as well. To prepare patients and their relatives for long-term prophylactic treatment, they should be informed about topics such as expected course of illness, treatment options, medication efficacy and side effects, use of a daily self-reporting instruments for mood to detect early warning signs of relapse or recurrence, long-term perspectives, and, if applicable, projected end of treatment. Patients should also be trained to distinguish between spontaneous, short-lasting mood-fluctuations (blips), and true emergence of a new episode which should be treated as soon as possible (Rush 1999).

Continuation Treatment
After initial remission from acute depression, continuation treatment should ensure stabilization, prevention of early relapses, and further improve functionality and promote reintegration. When antidepressant treatment has been effective and the primary goal of symptomatic remission has been achieved, it is usually recommended to continue the antidepressant in unchanged dosage for continuation treatment, unless side effects force tapering of the medication. The prophylactic effect of continuing antidepressant medication has been shown in a multitude of studies (Geddes et al. 2003) (see Figure 66–2). In a systematic review, Hirschfeld found that one-third to half of patients successfully stabilized in acute-phase treatment will relapse if medication is not sustained throughout the continuation period, whereas only 10–15% relapse if medication is continued (Hirschfeld 2001). It is also wise to continue the full dose during the maintenance treatment: patients who received only half of the acute phase dose of imipramine or paroxetine during maintenance therapy showed a significantly higher recurrence rate (Franchini et al. 1998, Frank et al. 1990). Thus, the often applied clinical practice of dose reduction during maintenance treatment lacks evidence and may put the patient at an increased risk of relapse. When full response is achieved with low dose acute antidepressant treatment, it may be justified to continue treatment in the lower dose range (Furukawa et al. 2003).

It is generally recommended to continue the effective antidepressant monotherapy or combination treatment for at least another 3–6 months (Hirschfeld 2000) (see Table 66–2) but at least until all symptoms have totally subsided, as residual symptoms are predictive for early relapse (Ramana et al. 1995). Patients with a history of previous long lasting episodes or several risk factors of recurrence (Nierenberg et al. 2003) (see Table 66–3) may be candidates for longer continuation treatment.
Prophylaxis of New Episodes

If a decision for long-term maintenance treatment (prophylaxis against new depressive episodes) has been made, the transition from continuation to prophylaxis is not clear-cut. However, if there is no indication for prophylaxis or the patient refuses to continue on medication, a period of slow tapering off at the end of the continuation period is strongly advised. It has been suggested that the tapering phase should last at least 4–6 months (Bauer et al. 2002b).

Maintenance treatment is recommended for patients with recurrent episodes, especially when more than one episode (prior to the present one) has occurred during the last 5 years or when remission has been difficult to achieve. Other factors influencing the decision regarding maintenance treatment include both the number and severity of previous episodes, the duration of previous symptom-free intervals, the comorbid presence of other psychiatric or medical illnesses, as well as the presence of suicidal ideation. In patients with more than two or three relapses, year-long or sometimes life-long prophylactic treatment has been recommended, for example, the World Federation of Societies for Biological Psychiatry Guidelines recommend maintenance treatment of 5–10 years for patients with recurrent episodes not at special risk, for example, without genetic preposition, comorbidities or difficult psychosocial circumstances. They consider life-long maintenance in patients at greater risk, for example, with more severe episodes, and especially when two or three attempts to withdraw medication have been followed by another episode within a year (Bauer et al. 2003). Another apparent risk factor for recurrences is insufficient responsiveness during acute treatment trials: with two or more acute treatment trials to achieve remission, the average probability of a relapse within a 1 year follow-up increases, from 33.5% if only one to 50% if four treatment steps were needed (Rush et al. 2006b).

Combining an antidepressant with lithium may not only improve relapse prevention (Sackeim et al. 2001) but also be more protective against suicide (Müller-Oerlinghausen et al. 2006). Once stabilized on this combination, it is not wise to withdraw lithium for at least a year (Bschor et al. 2002).

Where these recommendations are laid out for MDD, the advantages of continuation treatment may be less obvious in patients with long symptom-free intervals and/or only mild depression, and may not always outweigh the risks of some long-term pharmacotherapies, for example, hepatic or renal malfunction.

The chances of relapse decrease and the prognosis improves with time elapsed since discontinuing medication. The risk of a depressive relapse is 60% on placebo (compared to 29% on antidepressants) after 1 year. For the second and third year, the risk of relapse is reduced by 50% compared to the first year and may continue to decline (Geddes et al. 2003). Thus, decisions on long-term treatment must be made on an individual basis, taking into account the patient’s past experience with longer medication-free intervals, if any.

For some patients, long-term treatment may lead to worse outcomes. A literature review by Fava (Fava 2003) raised the question of whether at least a substantial subgroup of depressed patients may not only have no benefit from maintenance medication, but even experience a worsening of the long-term course of the illness. According to Fava, the mechanism of this paradoxical effect may include tolerance to antidepressants in long-term treatment, onset of resistance upon each challenge with the same antidepressant, and withdrawal symptoms, with sudden discontinuation of antidepressants leading to destabilization. Fava speculates that continued drug treatment may initiate biological processes counteracting the initial acute effects of a drug and may result in loss of clinical effectiveness. With sudden drug discontinuation, these processes may operate unopposed at least for some time and increase vulnerability to relapse.

Alternatives to Antidepressants for Prophylactic Treatment: Lithium and Anticonvulsants

If patients are not responsive to prophylactic antidepressant treatment or do not tolerate side effects, the first alternative is long-term lithium maintenance therapy. Although it may be even more efficacious in bipolar disorder and despite some negative published results in unipolar disorder (Burgess et al. 2001), the efficacy of lithium in preventing relapses in unipolar recurrent depression has been well established (Paykel 2001). Besides preventing new episodes, lithium has been demonstrated to normalize the mortality rates for cerebrovascular and cardiovascular disorders in affectively ill patients (Angst et al. 2002a). Combined lithium and antidepressant treatment reduces the risk of suicide to a significantly larger extent than antidepressants alone (Guzzetta et al. 2007). The usually recommended serum lithium levels for prophylaxis in unipolar recurrent depression are 0.5 to 0.8 mmol/L, but individual variations may occur.

Carbamazepine has been compared in two small double-blind trials with lithium in recurrent major depression, with results suggesting equal efficacy for lithium and carbamazepine (Blacker 1996). However, when using carbamazepine its capacity not only to induce its own hepatic metabolism, but also to accelerate metabolism of other drugs that are metabolized by CYP 3A4 needs consideration. Some antidepressants, for example, venlafaxine, nefazodone, reboxetine, and imipramine are substrates of CYP 3A4 and thus may not achieve sufficient plasma levels when used in combination with carbamazepine. CYP 1A2 and CYP2C9, which contribute also to carbamazepine metabolism, may also be inhibited by fluvoxamine. With these potential interactions and the limited scientific evidence from placebo-controlled studies, carbamazepine can only be recommended when other strategies have failed.

For other anticonvulsants only anecdotal reports and small case series have been published for prophylaxis in unipolar depression, but no controlled studies.

Somatic Treatments

Antidepressant Pharmacotherapy: General Considerations
The treatment portfolio in depression includes pharmacotherapy, psychotherapy, and sociotherapy. Pharmacotherapy is not always mandatory for less severe forms of depression, whereas severe depression usually requires pharmacotherapy or electroconvulsive therapy (ECT). In addition, a variety of other biological interventions such as sleep deprivation and bright light therapy may be effective in certain patient subgroups.

The discovery of TCAs was a milestone in the treatment of depression. However, despite their undoubted effectiveness, it soon became apparent that their anticholinergic and antihistaminergic side effects could cause problems. New antidepressants have been developed with a more selective mode of action to try to avoid these side effects. In the following section, we describe the modern antidepressants according to their main mode of action, and subdivide the older tri- and tetracyclic substances according to their predominant action on serotonergic and noradrenergic neurotransmission.

Currently, TCAs and tetracyclic antidepressants with predominant serotonergic (e.g., clomipramine), noradrenergic (e.g., desipramine), or mixed serotonergic/noradrenergic (e.g., amitriptyline) action are available. In addition, selective and reversible inhibitors of monoamine oxidase A (RIMA, e.g., moclobemide), an irreversible MAO-B inhibitor (MAOBI, selegiline), nonselective and irreversible inhibitors of monoamine oxidase A and B (MAOI, e.g., tranylcypromine), selective SSRIs (e.g., citalopram), selective (NARI) (e.g., reboxetine\(^1\)), and antidepressants with a dual mode of action such as selective SNRI (e.g., venlafaxine), and NaSSA (e.g., mirtazapine) acting via blockade of \(\alpha_2\) and 5-HT\(_2\)-receptors are licensed. Furthermore, a dopamine and noradrenaline reuptake inhibitor (bupropion) and serotonin modulating antidepressants (e.g., trazodone) are available. The latest newly developed mechanism of action is the agonism at melatonergic MT\(_1\) and MT\(_2\) receptors and selective antagonism at serotonergic 5-HT\(_3\) receptors represented by the antidepressant agonomeline; FDA approval was still pending in late 2007. Other developments include the use of single enantiomers instead of racemic compounds, for example, escitalopram.

A summary of commonly used antidepressants including their primary mode of action and their influence on other receptor systems is shown in Table 66-4.

Despite the development of a variety of new antidepressants with different pharmacodynamic profiles, higher efficacy in comparison to older antidepressants has, so far, not been achieved. The latency of several weeks until the onset of sufficient therapeutic effects remains a serious and clinically relevant problem. A faster onset of response has been described in some publications for newer dual-action compounds, for example, mirtazapine and venlafaxine, but the clinical relevance is still controversial (Blier 2003). The only two methods for achieving more rapidly occurring, but in most cases unfortunately not sustained, antidepressant effects are sleep deprivation (Wu et al. 1990) and ECT (ECT Review Group 2003).

The usually recommended daily dosages for both starting and maintaining antidepressant treatments are presented in Table 66–5.

Management of Medication Side Effects
Minor side effects are common and associated with the majority of antidepressants, both old and new but the side effect profile differs. Patient complaints about side effects should always been taken seriously, otherwise nonadherence and unsupervised discontinuation will be the consequence. Patients do not always spontaneously report side effects, so active questioning is needed and somatic symptoms and concerns attributed to the medication by the patient need to be distinguished from symptoms of depression.

Summary of Side Effects
Antidepressant drugs can produce common side effects according to their receptor profiles. In addition, although rare, they may cause discontinuation symptoms, allergic reactions and blood dyscrasias.

Anticholinergic and antihistaminergic side effects may complicate the use of TCAs. In case of overdose, cardiovascular complications are more frequent then with other antidepressants, although they may also occur with newer antidepressants such as SSRIs (Pacher et al. 1999). Newer antidepressants have considerably fewer anticholinergic effects, but it is important to pay attention to their specific side effect profiles. In particular, the activating properties of NARI can cause tremor and restlessness together with sleep disturbances. SSRIs raise serotonin levels at multiple sites and at multiple receptors throughout the brain (Stahl 1998) and may cause nausea, headache, agitation, and a general activation syndrome, sexual dysfunction, and sometimes sleeplessness. Substances with additional antihistaminergic properties such as mianserin, mirtazapine, or doxepine may induce drowsiness at treatment onset, and later often increased appetite and weight gain (Kent 2000).

The specific side effect profiles of antidepressants are summarized in Table 66–6. In combination with Table 66–4 the specific side effect profile which can be expected using a specific antidepressant can be deduced.

The discontinuation of antidepressants may also elicit adverse events, sometimes mistaken as signs of dependence. A sudden stop of treatment may provoke discontinuation symptoms which have been described for numerous classes of antidepressant drugs (particularly frequent with MAO inhibitors, venlafaxine and SSRIs, especially paroxetine, and less frequent with fluoxetine and escitalopram) (Baboolal 2004, Haddad 1998, Rosenbaum et al. 1998, Schatzberg et al. 2006). Typical features of addiction, however, such as increasing tolerance and compulsive use, are missing with antidepressants\(^1\). Only bupropion, used as an antidepressant and for smoking cessation, has been a matter of controversy, but the compound is not amphetamine-like and an abuse potential is very unlikely in humans (Griffith et al. 1983, Miller and Griffith 1983).

A discontinuation syndrome manifests itself mostly as a “Flu-like” syndrome including agitation, sleep-disturbances, sweating, gastrointestinal discomfort, and headache. It may become particularly dramatic in newborns whose mothers
were treated with serotonergic drugs until delivery (Wen et al. 2006). The onset of symptoms occurs within 2 days on average (Bogetto et al. 2002) and they may take up to 2 weeks to subside. Discernible effects are more likely with high doses and prolonged treatment. With less than 5 weeks of exposure, withdrawal effects are quite unusual and unexpected. Besides the acute harassment, discontinuation symptoms may stress the therapeutic alliance by weakening confidence in the practitioner’s advice (Garner et al. 1993), and put the patient at risk of an early relapse (Fava 2003, Harvey et al. 2003).

### Consequences for Treatment

- side effects are tolerable for the short, but not long term
- full or at least partial remission has been achieved
- and the patient is still willing to continue on the medication despite having experienced side effects, careful tapering down of the medication until side effects fade would be the first step. If side effects occur at low doses, therapeutic drug monitoring may be helpful. If side effects do not subside or efficacy is lost after tapering of...
medication, switching to an antidepressant in another class is advised.

If a discontinuation syndrome occurs, it can usually be abolished by re-starting the withdrawn drug followed by slow tapering off.

For the management of side effects, education of the patient plays an essential role. Experiencing side effects is less frightening if the patient is aware about their possibility. Especially with side effects that may subside after some days, such as increased sleepiness, informed patients may be more likely to tolerate them and to stay on the medication.

**Blood Dyscrasias and Disturbance of Erythro- and Leucopoiesis During the Use of Antidepressants**

Neutropenia and thrombocytopenia have been observed during treatment with mood stabilizers like carbamazepine, lamotrigine, or valproate. During antidepressant exposure with a variety of substances, including TCA or tetracyclic substances such as mianserin, neutropenia has also been reported. For the newer antidepressants, inconsistent case reports have been published for SSRI, venlafaxine, and mirtazapine.

### Treatment-Emerging Suicide and Suicidality

Evidence that a given antidepressant increases suicide rates can not be derived from a single randomized controlled trial. Fortunately, suicide is still such a rare event that it can not serve as a primary outcome criterion (besides the fact that such a prospective study would be unethical). Thus, less clearly defined parameters as “suicidality,” including suicidal ideation, preparation for suicide, suicide attempts, but sometimes just the wish to be dead (which is a common symptom and indicative for the severity of depression, have to serve for detecting a potential suicide risk. As we do not know the exact relationship between what is, partially arbitrarily, defined as suicidality and completed suicide, the methodological basis for assessing suicide risk becomes weak.

Following several case reports in the 1990 on new-onset suicidality with fluoxetine, especially in children and adolescents, the FDA commissioned an independent group of investigators at Columbia University to review all untoward adverse events that suggested suicidal-like activity in controlled trials of SSRIs in children and adolescents. In 4,400 depressed children and adolescents in a total of 24 studies, there were no completed suicides; however, the risk of suicidal-like ideation or activity was 4% on active medication and 2% on placebo (US Food & Drug Administration 2005). The exact significance of this finding is not clear and the FDA did not make any conclusions regarding causality. A similar finding of increased risk of suicide attempts (OR: 2.28), but not of completed suicides has been reported in a recent meta-analysis of 702 RCTs primarily in adult patients (Fergusson et al. 2005). However, two other meta-analyses found no evidence that SSRIs increased the risk of suicide (Gunnell et al. 2005, Hammad et al. 2006).

Another source of information is naturalistic follow-up studies. Grunebaum et al. (Grunebaum et al. 2004) presented the results of a methodologically very sound analysis of US registries for the years between 1985 and 1999. Prescription rates for SSRIs and other newer antidepressants were both inversely associated with suicide rates. In a multivariable analysis adjusting for unemployment and alcoholic beverage consumption rates, SSRI antidepressant prescription rates remained inversely associated with the national suicide rate, suggesting an overall antisuicidal effect of medication. It is also of note that with the decline of antidepressant prescription in the US due to the FDA black box warning, suicide rates have increased again (Gibbons et al. 2007).

The effect of antidepressants on suicidality needs further evaluation. If at all, there may be more compelling evidence in adolescents than in adults. A potential explanation may be a higher rate of substance abuse or an undetected bipolar disorder with mixed symptomatology. Both underlying conditions may become harmful together with the activating, sometimes agitating effects, especially of SSRI and some SNRI. In adults, the more compelling evidence is for an antisuicidal effect of antidepressant treatment, generated

SSRIs

Efficacy

SSRIs are the most frequently prescribed antidepressants as a first line treatment (Ostacher et al. 2005). Despite their similarities, some characteristics differ among SSRIs (see Table 66–7). Good efficacy has been described for each of the currently available substances, regardless of the etiology or severity of depression. Available data suggest that, within the group of SSRIs, escitalopram may be the most powerful (Llorca et al. 2005). A pooled analysis of all available study data found significant advantages of escitalopram in comparison to several SSRIs such as citalopram, fluoxetine, and sertraline and also in comparison to the SNRI venlafaxine (Kasper et al. 2006).

Some other antidepressants may be superior to SSRIs (venlafaxine (see e.g., Cipriani et al. 2006), milnacipran (see e.g., Puech et al. 1997), mirtazapine (see e.g., Thase et al. 2006a), but it is difficult to interpret the clinical meaning of these results. Compared to TCAs, the overall efficacy of SSRIs appears similar (Geddes et al. 2000), but MAOI may have an advantage over SSRI in treatment-resistant patients and those showing atypical features of depression (see Section, “Other Clinical Features with Possible Impact on the Course and Treatment Outcome”).

Safety and Tolerability

Most studies agree that the safety and tolerability profile of SSRIs as a pharmacological group of compounds is considerably better than that of TCAs (Cheeta et al. 2004, Mace and Taylor 2000). Since SSRIs have fewer anticholinergic effects, they have lower cardiovascular toxicity together with a lower risk for constipation and urinary retention. Other anticholinergic side effects, for example, effects on the visual system such as an enhanced risk for worsening of an angle-closure glaucoma and accommodation disturbances, are also rare using SSRIs5. The most frequent side effects

</table>
after short-term SSRI treatment are gastrointestinal discomfort such as nausea, diarrhea, or emesis. Also common are restlessness and agitation, sleep disturbances, dizziness, and headache. During long-term SSRI treatment sexual dysfunction such as loss of libido, anorgasmia, and in men disturbances of erectile or ejaculatory function may become a significant limitation. In long-term treatment, SSRI are also associated with discontinuation syndromes, especially paroxetine (Trenque et al. 2002).

Disorientation, restlessness, myocloni together with hyperreflexia, tremor, and pain-syndromes together with unstable vital signs are symptoms of the potentially fatal serotonin syndrome (Boyer et al. 2005). It occurs predominantly as an interaction of SSRIs with MAOIs or other serotonergic substances (e.g., S-TCAs or triptans used during acute therapy of migraine attacks), even before and after treatment with the SSRI, depending on the half-life of the other medication, but rarely during SSRI monotherapy.

Rare side effects of SSRIs are weight gain, anticholinergic effects or extrapyramidal motor side effects. A very rare adverse event during SSRI therapy of younger, but a not uncommon event in elderly patients, is an inappropriate secretion of antidiuretic hormone possibly causing an electrolyte imbalance and hyponatriemia with an increased risk for seizures (Degner et al. 2004). Finally, the combined use of SSRIs and substances increasing the risk of bleeding, for example, nonsteroidal anti-inflammatory agents or aspirin, is discouraged due to a blockade of serotonin reuptake in platelets and subsequent platelet dysfunction (Serebruany 2006).

### Selective Serotonin and Noradrenaline Reuptake Inhibitors

#### Efficacy

SNRIs represent a group of antidepressants with a dual mode of action, on both serotonin and norepinephrine reuptake. Today, three substances of this group, venlafaxine, milnacipran, and duloxetine, are available. Response rates from clinical trials with venlafaxine and duloxetine are comparable, but venlafaxine has shown a trend to be more favorable in achieving remission (Vis et al. 2005). In comparison to SSRIs, venlafaxine appears equally effective as sertraline and escitalopram, but may be more potent than fluoxetine and paroxetine (Cipriani et al. 2006). For milnacipran, meta-analysis has shown an antidepressant efficacy similar to that of imipramine and significantly superior to that of SSRIs (Puech et al. 1997). Direct comparisons between duloxetine and paroxetine in RCTs displayed inconclusive results, and no significant difference was observed between duloxetine and escitalopram (Hirschfeld et al. 2004).

Direct comparisons between SNRIs (venlafaxine and milnacipran) and TCAs showed no significant or clinically relevant differences in efficacy (Samuelian and Hackett 1998, Van Amerongen et al. 2002).

#### Safety and Tolerability

SNRI treatment shows a favorable tolerability profile when compared with TCAs, with most adverse events occurring early in treatment and tending to decrease or disappear with continued treatment (Stahl et al. 2005). For venlafaxine an extended release formulation is available that improves tolerability in comparison to the immediate release formulation. High dose therapy with venlafaxine may cause hypertension (Thase et al. 2006b). The risk of elevated blood pressure seems to be less prominent in newer SNRIs such as duloxetine and milnacipran (Stahl et al. 2005).

In case of overdose, the fatal toxicity index of venlafaxine seems to be in between SSRIs and TCAs (Koski et al. 2005), therefore some guidelines recommend to use SNRIs only as a second-line treatment after SSRIs have failed (Medicines and Healthcare products Regulatory Agency 2006, National Institute for Health and Clinical Excellence 2004).

*Modified according to Stahl (1997, 2006).*
Safety and Tolerability
In all published studies, reboxetine displayed a good safety and tolerability profile (Burrows et al. 1998). Sexual dysfunction appears less common with reboxetine than with the SSRI fluoxetine (Clayton et al. 2003). Less frequent than with SSRIs, reboxetine treated patients may also experience agitation and sleep disturbances. Due to α-receptor agonistic effects reboxetine may cause hyperhidrosis and urinary retention despite its low anticholinergic activity.

α-Receptor Blocking Tetracyclic Antidepressants

Efficacy
The structurally related TCAs mianserin and mirtazapine represent the α₂-receptor blocking antidepressants. Mianserin was developed first and shows a higher affinity for the α₁-adrenoceptor and higher noradrenergic reuptake compared to mirtazapine (Kelder et al. 1997). Mirtazapine is characterized in its own class with noradrenergic and specific serotonergic properties (NaSSA). The α₂ antagonistic effect in the case of mirtazapine results in serotonergic activation, whereas with mianserin, the α₁ antagonistic effect counteracts the α₂ antagonistic effect.

Both mianserin and mirtazapine are at least as effective as TCAs and have some advantages in comparison to other newer antidepressants (Szegedi et al. 2005). Especially in the common case of insomnia accompanying a depressive disorder, mirtazapine significantly improves sleep quality in addition to its antidepressant effects (Thase 1999). Limited evidence suggests a more rapid onset of antidepressant action with mirtazapine in comparison to SSRIs (Blier 2003).

Safety and Tolerability
In comparison to TCAs, NaSSAs exert a substantially better side effect profile (Tran et al. 2003). The safety in overdose is similar to that of SSRIs (Olver et al. 2001), but typical serotonergic side effects such as sexual dysfunction and gastrointestinal complaints are less frequent in mirtazapine-treated patients (Montgomery 1995). The most commonly reported adverse events during mirtazapine therapy are related to antihistaminergic properties, such as initial somnolence and dizziness, together with increased appetite and consecutive weight gain in the long run (Tran et al. 2003). Potentially fatal side effects are rare, but clinicians have to be aware of possible neutropenia both with mianserin and mirtazapine (Ozcanlı et al. 2005). In addition, a rare risk of agranulocytosis has been reported for mianserin.

Unselective Monoaminoreuptake-inhibitors/TCAs
From the introduction of the first antidepressant, imipramine, tricyclics were the cornerstone in the treatment of depression for a long time. Over the last decade, however, tri- and tetracyclic antidepressants have lost their leading role, partly due to their tolerability problems, partly due to the emergence of new treatment alternatives. Clinically, it can be useful to subdivide TCAs not only according to their sedating or activating properties, but also according to their effects on serotonergic, noradrenergic, and dopaminergic neurotransmission. In case of treatment failures and pharmacotherapy resistance, switching from serotonergic to noradrenergic or mixed acting TCAs seems plausible, but controlled studies supporting this approach are still lacking.

Efficacy
TCAs are still an effective treatment of depression independent of its severity. Controlled studies comparing TCAs with other classes of antidepressants were described above. Especially in severely depressed hospitalized patients, mixed serotonergic/noradrenergic tricyclics seem to perform better than SSRIs (Anderson et al. 2000) or the RIMA Moclobemide (Danish University Antidepressant Group 1993). Based on clinical experience, but without controlled evidence, TCAs with less significant sedating effects, such as clomipramine or desipramine, seem to be more suitable in retarded and anergic depression. TCAs with inherited strong antihistaminergic effects such as doxepine, amitriptyline or doxepine may have advantages in agitated patients with significant sleep disturbances.

Safety and Tolerability
The main concerns in using TCAs as a first line treatment are anticholinergic and antihistaminergic side effects. Sedating properties may be of use in the treatment of depression-related sleep disturbances, but daytime drowsiness and sedation often lead to discontinuation of treatment. In the long run, increased appetite, a consequent weight gain and in some cases the risk of metabolic syndrome becomes crucial.

Caution is warranted in suicidal patients due to the higher cardiotoxicity of tri- and tetracyclics in comparison with the more selective newer antidepressants.

Glutamatergic Modulation/Other Modes of Action

Not Directly Involving Monoamines—Tianeptine
Despite its modified tricyclic structure, initial studies showed that the modified TCA tianeptine did not share common pharmacological properties with other TCA, MAOI, or SSRI antidepressants (Wilde and Benfield 1995). Following chronic administration, tianeptine induces adaptive changes in cortical, but not hippocampal serotonin transporters (Pineyro et al. 1995a, Pineyro et al. 1995b) and has neuroprotective effects that contribute to antidepressant properties (McEwen et al. 2005). Tianeptine has been shown to change the neuronal architecture of the hippocampus and amygdala, the rate of apoptosis in the hippocampus and temporal cortex and to restore the hippocampal volume following exposure to chronic stress (McEwen et al. 2005). These effects have been explained in terms of modulation of glutamatergic transmission (Reagan et al. 2004).

Efficacy
In published RCTs, the efficacy of tianeptine was comparable to SSRIs (Kasper and Olie 2002), amitriptyline (Invernizzi et al. 1994) and mianserin (Brion et al. 1996).

Safety and Tolerability
Tianeptine does not appear to be associated with severe anticholinergic or cardiovascular side effects (Loo and Deniker 1988). The overall tolerability profile is comparable to SSRIs in general and better than that of paroxetine (Kasper and Olie 2002).
MAOls

Efficacy
A comparison of all available irreversible MAOls reported similar efficacy to TCAs, but MAO treatment may be especially efficacious in patients suffering from depression with anergic or atypical features (Henkel et al. 2006). In treatment-refractory depression, the use of supra-therapeutical doses of MAOI has been proposed, but only few clinical data support the effectiveness in refractory depression (Adli et al. 2005). Irreversible MAOls are mostly considered as a subordinated treatment choice because of their potential to cause serious adverse events.

Selegiline, an MAO B inhibitor predominantly used in the therapy of PD, may exert significant antidepressant effects (Amsterdam 2003, Bodkin et al. 2002). A selegiline patch has been approved as an antidepressant by the FDA. This is the only antidepressant patch approved so far, and it may be a useful tool in patients who tend to forget to take medication.

Reversible inhibitors of monoaminooxidase A (RIMAs) are considered to be as effective as TCAs and SSRIs, but somewhat less effective than irreversible MAOIs (Bonnet 2003).

Safety and Tolerability
MAOls in combination with other sympathomimetic medications or tyramine-rich food may provoke a hypertensive crisis demanding, immediate treatment, for example, phenelzine, therefore dietary restrictions are necessary (Brown and Bryant 1988). These restrictions are not necessary when using RIMAs, however, at doses the risk of interactions with tyramine might again become clinically relevant (Bonnet 2003). In case of the selegiline transdermal patch, dietary modifications are necessary when using higher dose ranges (9 or 12mg/day).

Discontinuation symptoms including agitation, anxiety, sleeplessness or drowsiness, and even hallucinations and delirium have been described for MAOI (Dilsaver 1988). The risk for a serotonin syndrome due to the concomitant use of or accidental combination with other serotonin-enhancing antidepressants has to be kept in mind. Depending on the half-life of the substances, a drug-free interval of at least 2 weeks in case of a serotonergic medication before or after irreversible MAOls is necessary to be on the safe side. In case of the prescription of MAOls after fluoxetine, the interval has to be extended up to 5 weeks; in case of prescribing serotonergic substances after the RIMA moclobemide, it can be shortened to 3 days.

Serotonin Modulating Antidepressants

Efficacy
Nefazodone and its structural analog trazodone block 5-HT2 receptors, but only modestly inhibit the reuptake of serotonin and noradrenaline (Blier et al. 2007). Both medications have proven antidepressant efficacy in RCTs and comparator trials (DeVane et al. 2002, Haria et al. 1994). Due to their sedating properties, nefazodone and trazodone appear particularly suitable for agitated patients and patients suffering from insomnia (Boerner and Möller 1999, Thase 1999).

Safety and Tolerability
SMAs have a similar safety margin to TCAs, but are better tolerated (Lader 1996) due to lower anticholinergic and antihistaminergic activity. The most common side effects are sedation, dry mouth, nausea, somnolence, and dizziness (Cyr and Brown 1996). For trazodone, cases of priapism have also been reported, which led to it being investigated as an agent for erectile dysfunction (Fink et al. 2003).

However, several case reports of severe hepatotoxicity leading sometimes to fatal hepatic failure have been published for nefazodone, so that intensive clinical and laboratory monitoring is advised (Lucena et al. 2003). As a result, the original producer has withdrawn nefazodone from the market, but it is still available as a generic substance.

DNRI
Currently, this class contains only one medication, bupropion; however, its mechanism of action is not as clear as the class name suggests. It is thought to be related to inhibition of presynaptic dopamine and noradrenaline reuptake transporters (Foley et al. 2006), but within the therapeutic dose range of bupropion, PET scan studies in humans found no effects on dopamine or noradrenaline transporters (Kugaya et al. 2003).

Efficacy
In RCTs, bupropion showed significant antidepressant efficacy with an at least equal effect size in comparison to different SSRIs, namely sertraline, fluoxetine, and paroxetine, as well as in comparison with the TCAs amitriptyline, imipramine, and doxepine and the SNRI venlafaxine and the SMA trazodone (Foley et al. 2006).

Safety and Tolerability
In comparison to the SSRIs sertraline and fluoxetine, bupropion-treated patients showed a lower rate of serotonergic side effects such as sexual dysfunction, gastrointestinal complaints, insomnia, and agitation (Hansen et al. 2005). Sexual dysfunction in male patients may be especially prominent but can be reduced by using an extended release formulation. Generalized seizures are considered to be a rare event in patients without risk factors (Montgomery 2005), but still more frequent than with other antidepressants, especially in conditions that increase the risk for seizures such as alcohol withdrawal, anorexia, or bulimia (Horne et al. 1988).

Antidepressants Targeting Melatonergic Neurotransmission
A variety of animal studies and clinical trials in depressed patients suggest that agomelatine, a synthetic melatonergic MT1 and MT2 receptor agonist with serotonin (5-HT1C receptor antagonist properties within the central nervous system, has antidepressant effects. This has been confirmed together with a good tolerability profile in several trials (Montgomery and Kasper 2007) comparing agomelatine to established antidepressants such as paroxetine and venlafaxine. Sleep-related complaints were especially ameliorated without sedation during daytime.

A randomized, double-blind, multicenter study demonstrated the absence of discontinuation symptoms in sustained remitted patients when stopping agomelatine (Montgomery...
In summary, agomelatine represents a promising novel strategy in the treatment of depression, but its approval is still pending.

**Herbal preparations Used in the Treatment of Depression—St. John’s wort**

It is a matter of ongoing controversy whether herbal preparations used in the treatment of depression should be classified as antidepressants (Bauer et al. 2002b), although they make up a reasonable share of antidepressant prescriptions in several countries. The main reason is that RCTs could not prove that these medications are useful in severe MDD; another reason is their insufficiently defined mechanism of antidepressant action.

**Efficacy**

Most studies have concentrated on the use of St. John’s wort (Hypericum perforatum). Many different preparations of St. John’s wort are available in over-the-counter packages that differ in the number and concentration of active and inactive, helpful and potentially harmful constituents. Both serotonergic mechanisms and MAO inhibition as antidepressant modes of action have been discussed (Del-tito and Beyer 1998). Although promising in small RCTs against fluoxetine, sertraline, paroxetine, and imipramine, St John’s wort did not separate from placebo in a sufficiently powered RCT (Shelton et al. 2001), and a recent meta-analysis also shows inconsistent results (Linde et al. 2005).

**Safety and Tolerability**

Comparative studies suggest a significantly better tolerability of St John’s wort in comparison to SSRIs and TCAs. In particular, hypericum therapy was devoid of anticholinergic side effects, sedation, gastrointestinal disturbances, and sexual dysfunction (Trautmann-Sponsel and Dienel 2004). Because its mechanisms of action involve serotonergic mechanisms or monoamine-oxidase inhibition, concurrent use of St John’s wort together with SSRIs and MAOIs should be avoided (Deltito and Beyer 1998) as a serotonin syndrome could theoretically occur.

**Ω3 Polyunsaturated Fatty Acids**

**Efficacy**

After the publication of a potential epidemiological link between low fish intake and depression (Hibbeln 1998), low Ω3 fatty acid levels in depressed women during the perinatal period have been found (Rees et al. 2005). In four out of seven double-blind RCTs, a significant improvement of depressive symptoms could be seen after regular ingestion of eicosapentaenoic acid, an Ω3 fatty acid, as an adjunct to antidepressant treatment in comparison to placebo (Nemets et al. 2002, Peet and Horrobin 2002). A small study in postpartum depression established a dose range of 0.5 to 2.8 g/day as an effective dosage (Freeman et al. 2006).

However, other RCTs failed to show antidepressant effects of Ω3 fatty acids (see e.g., Silvers et al. 2005). Furthermore, it remains unknown whether Ω3 fatty acids substitution is effective only in patients with abnormally low Ω3 fatty acid levels or in all depressed patients.

**Safety**

The safety and tolerability profile of Ω3 fatty acid therapies seems to be unproblematic. Only diarrhea is a common side effect. As Ω3 fatty acids are considered cardioprotective, an additional benefit for depressed patients who have an elevated cardiovascular risk has been proposed and should be investigated further (Frasure-Smith et al. 2004).

**Treatment Refractory Depression**

A general problem in pharmacotherapy of depression is the likelihood of nonresponse to the first antidepressant treatment (Rush 2007). Up to 50% of depressed patients do not respond sufficiently to a first course of an adequate antidepressant treatment (about 30% do not show sufficient improvement; about 20% drop out due to tolerability problems). Half of patients also fail to respond to a second antidepressant treatment trial. If several antidepressant treatment trials have been unsuccessful, response rates after switching to another drug are likely to decrease further (Fava et al. 2006) and long-term prognosis worsens (Rush et al. 2006b).

Patients who do not respond to at least two antidepressant monotherapies (in some wider definitions even one) are often defined as treatment resistant. However, reasons for such “treatment resistance” or “nonresponse to antidepressant treatment” may vary and often do not reflect true resistance to treatment. The definition by Ananth (Ananth 1998) as a “failure to respond adequately to two successive courses of monotherapy with pharmacological different antidepressants given in adequate dose for sufficient length of time” includes a number of prerequisites: correct diagnosis, adequate treatment in terms of dosage, duration, and compliance and unsuccessful previous therapy.

Biological hypotheses for therapy resistance are undiagnosed medical conditions maintaining depression or an abnormal drug metabolism (Rush et al. 2003). Other factors which may also lead to less favorable outcomes include alcohol- and substance abuse, personality disorders, and anxiety and panic disorder (Adli et al. 2005). Sharan and Saxena (1998) have identified several other factors predictive for poor response including a family history of affective disorders, severity of depression, suicide attempts, number of previous episodes, long duration of depression prior to treatment, negative life events, and poor social support. There is an obvious impact of social and environmental factors on chronicity of depression, specifically the interaction of cognitive and interpersonal factors and early adversity in maintaining and prolonging depressive episodes (Lara et al. 1999). For this reason, some experts point out that treatment with CBT and IPT needs to precede the decision that the condition is treatment resistant (Thase et al. 1997).

As described below, several pharmacological treatment strategies are suitable to deal with treatment refractoriness, including increase of dosage, switch to an antidepressant of the same class, switch to an antidepressant of another class, combination therapies with more than one antidepressant, and pharmacological and nonpharmacological augmentation strategies. However, it is impossible to predict the most effective treatment strategy for an individual patient. Strategies to enhance therapeutic effectiveness such as lithium
Psychopharmacological Strategies in Case of Nonresponsiveness to Antidepressant Treatments

**Dose Escalation Strategies**
Before switching antidepressants, sufficient length of treatment and the adequacy of dosage should be considered. If in doubt, therapeutic drug monitoring may help ensure adequate blood levels of medication (Corruble and Guelfi 2000). Adli et al. (2005) conducted a systematic review of whether dose escalation may lead to additional benefit after a medium-dose treatment fails. They found some evidence that this may be true for TCA, but not for SSRIs.

When the previous monotherapy was not efficacious at all, even at maximum dosage, the question arises which medication to test next. Whereas most guidelines recommend a switch to an antidepressant with another mode of action, this is not necessarily true. A recently published analysis of the Star*D trial pointed out that approximately 25% of patients non-responsive to citalopram may benefit from switching not only to bupropion or venlafaxine, but also sertraline (Rush et al. 2006c). Figure 66–3 summarizes a step-wise approach for management of nonresponsiveness to the first antidepressant.

**General Introduction to Combination and Augmentation**
With a partial response it may often be unwise to discontinue the medication and risk worsening of symptoms. Thus, combination with another antidepressant or augmentation should be considered, and there is now sufficient evidence that combinations of antidepressants or augmentation strategies are more effective than monotherapy in some patients (Kennedy et al. 2001). Combination treatment is defined as the addition of another medication without expecting potentiation of efficacy of the previous drug. Benefits as well as side effects are additive. Usually, a medication with a different pharmacology or a drug with a dual mechanism of action is chosen for combination treatment. In contrast, augmentation means the addition of another agent which by itself may be not specifically helpful as a primary treatment of depression, but may enhance responsiveness to a given antidepressant. Such agents include lithium, thyroid hormones, pindolol, buspirone, and some atypical antipsychotics. Table 66–8 summarizes common augmentation strategies.

*Modified from WFSBP Guidelines for Biological Treatment of Unipolar Depressive Disorders, Part 1 (Bauer et al. 2002b).

**Combination Treatment**

**Combination of Different Antidepressants**

**Efficacy.** Despite limited evidence, combination of antidepressants is a very common strategy. In a recent literature search, Dodd et al. (Dodd et al. 2005) identified only 8 randomized trials between 1978 and 2004 studying combinations of antidepressants, five of them including fluoxetine. Combining antidepressants with predominant serotonergic and noradrenergic properties, for example, SSRIs and SNRIs or SSRIs and NaSSAs, is one of the most frequently used therapeutic options (de la Gandara et al. 2005). Alternatively, combination of two dual-action substances such as mirtazapine and venlafaxine may be useful in case of prior treatment resistance, but controlled evidence is still missing.

**Safety and Tolerability.** Combining two or even more antidepressants may enhance tolerability when both antidepressants are used in lower doses (King et al. 1994). As an example, sexual dysfunction caused by SSRI treatment may be reduced when using lower dosages within combination strategies, for example, with bupropion which causes a lower rate of sexual dysfunction than some SSRIs. With other combinations, however, a variety of possible pharmacokinetic interactions may enhance the risk for severe adverse events, for example, an increased TCA toxicity due to cytochrome P450 inhibition by fluoxetine or fluvoxamine. Thus, the tolerability profile of combinations depends on both the dosages and the metabolism of the substances used and their specific side effect profiles which may be additive or supplementary.

**Combination of ECT and Antidepressants**

**Efficacy.** ECT as monotherapy may be sufficient to overcome treatment refractoriness (see Section, “Nonpharmacological Treatment Strategies”). The concomitant prescription of antidepressants during an ECT treatment course is quite frequent; typically either the patient was receiving medication prior to ECT, or it was introduced as pharmacological relapse prevention after ECT. In the first instance, the current recommendation is to maintain the antidepressant at a moderate dose during the entire course of ECT. There are reports of a putative acute benefit from combining ECT with TCAs, mirtazapine, or venlafaxine, but also of a lack of advantages with other concomitant medication like SSRIs (Baghai et al. 2006b).

**Safety and Tolerability.** The combination of ECT with therapeutic dosages of TCAs, SSRIs, and other modern antidepressants has been described as safe. The combination of ECT with MAOIs should be avoided, as lethal complications shortly after starting the pharmacological treatment have been described (Naguib et al. 2002). The combination of ECT with lithium may enhance somewhat the risks for anesthesia, prolonged seizures and transient cognitive impairment.

**Augmentation Treatment** Compared with switching antidepressants, augmentation strategies have some advantages. They eliminate the period of tapering out one antidepressant and introducing another, and usually build on a partial response. Consequently, if they work, augmentation strate-
gies can be rapidly effective; however, they may also raise tolerability and safety issues.

**Lithium**

Of all strategies listed in Table 66–8 which gives an overview on augmentation strategies, lithium augmentation has the best scientific evidence (Bschor et al. 2006). A multitude of open trials, 12 randomized, placebo-controlled trials, and a meta-analysis (Bauer et al. 2003) support the efficacy of lithium augmentation in the acute treatment of treatment-resistant unipolar depression. To allow full assessment of the patient’s responsiveness, lithium augmentation should be administered for at least 4 weeks, ensuring serum levels of 0.6–0.8 mmol/L (Bauer et al. 2002b). Once stabilized on the combination, it is not wise to withdraw lithium for at least a year (Bschor et al. 2002).

The utility of lithium augmentation may be limited by side effects, for example, polyuria, muscular weakness, or tremor. Especially in older patients, lithium toxicity may occur even within therapeutic plasma levels and might present itself with a clinical syndrome which is not always easy to differentiate from an increase in depression severity.

**Thyroid Hormones.** At least 13 prospective trials (nine open and four controlled double-blind studies) support the usefulness of triiodothyronine (T3), with most studies employing 25–35.5 μg/day (Bauer et al. 2002b). Women especially seem to have a favorable response to thyroid hormone augmentation (Altshuler et al. 2001). A recently published STAR*D report confirmed the similar efficacy of T3 and lithium with lower rates of adverse events and slightly (but nonsignificant) higher remission rates in the T3 group (Nierenberg et al. 2006). Recently, augmentation with i-thyroxine (T4) has been postulated as an alternative to T3, and open studies and functional neuroimaging support the efficacy of this approach (Bauer et al. 2005), however, double-blind controlled studies are still missing.

**Anticonvulsants**

Although large randomized, placebo-controlled monotherapy trials failed (Hurley 2002), lamotrigine may be of interest for the treatment of refractory unipolar depression. Retrospective chart reviews, open, randomized open label (Schindler and Anghelascu 2007) and controlled augmentation studies (Barbosa et al., 2007, Normann et al. 2002) are supportive of an antidepressant effect of lamotrigine addition in treatment resistant MDD.

For the older anticonvulsants, there is some evidence for augmentative efficacy of carbamazepine from open studies (Dietrich et al. 1998). However, studies also showed that carbamazepine augmentation stimulates the metabolism of venlafaxine and citalopram, therefore, it may be necessary to adapt the dose of the antidepressant accordingly (Ciusani et al. 2004, Steinacher et al. 2002).

Phenyletoin showed some efficacy in a comparator study against fluoxetine in patients with non-treatment-resistant depression (Nemets et al. 2005), but not in an augmentation study in SSRI non-responders (Kachkovskii and Kriukov 2006).

**Pindolol**

A potential role of 5-HT1A agonists in treating depression and anxiety has been a major focus of research in the past decade (Blier et al. 2003). Pindolol is a β-adrenoceptor antagonist. It also blocks 5-HT1A and 5-HT2A receptors and, therefore, should prevent the negative feedback effect of increased somatodendritic serotonin (Dawson et al. 2000), which may accelerate the onset of antidepressant action (Artigas et al. 2001, Artigas et al. 2006).

However, despite positive open studies, three out of four controlled trials have failed to show advantages over placebo in treatment refractory patients and only one small study applying once-daily high dose pindolol (7.5 mg) demonstrated a significant advantage (Sokolski et al. 2004). Thus, pindolol augmentation in treatment-resistant depression remains an experimental approach.

**Buspirone and Tansospirone**

Buspirone and tandospirone are partial 5-HT1A agonists and are believed to activate postsynaptic 5-HT1A receptors and thus may enhance the action of SSRIs. Buspirone has affinity to D1 and to a lesser extent D2 and D3-receptors in addition to α1 and α2-antagonistic activity (Millan et al. 2000). Recently, the STAR*D study investigated the efficacy of buspirone versus bupropion augmentation in SSRI non-responders. In most outcomes, the rate of improvement was similar for both strategies, however, buspirone was associated with more tolerability problems (Trivedi et al. 2006).

For tandospirone, there is so far only preliminary and weak evidence for antidepressant efficacy (Yamada et al. 2003).

**Second Generation Antipsychotics**

First generation medium potent antipsychotics, such as sulpiride, accelerate and improve antidepressant (SSRI) treatment (Uchida et al. 2005). More recently, the use of different atypical antipsychotics (see Table 66–8) to augment antidepressants in non-psychotic depressive disorder has been advocated. A recent meta-analysis (Papakostas et al. 2007) extracted data from 10 clinical trial reports involving 1500 outpatients with treatment-resistant MDD. Patients randomized to adjunctive treatment with an atypical antipsychotic agent were more likely to experience remission or clinical response (p = 0.001) than patients who received adjunctive placebo. However, these results are largely driven by trials involving olanzapine (see e.g., Shelton et al. 2005) or risperidone (see e.g., Mahmoud et al. 2007), whereas the evidence for other atypical antipsychotics is very limited and comparator studies to established strategies such as lithium augmentation are lacking.

Other Augmentation Strategies:

The serotonin precursors l-tryptophan and 5-hydroxytryptophan have been studied in depressive disorders with equivocal results. Some smaller studies using l-tryptophan showed potentiation of MAOIs and augmentation of serotonergic antidepressants in treatment-resistant depression for an overview see Nelson 2000) and in seasonal depression refractory to light treatment (Lam et al. 1997). However, unambiguous controlled studies are still lacking.

Since an open pilot trial by Wharton with methylphenidate (Wharton et al. 1971), the efficacy of stimulants in treatment-resistant depression has been documented in case series and one larger retrospective chart review (Stotz
et al. 1999). However, the only randomized controlled study could not find a significant advantage over placebo (Zhang et al. 2000).

More recently, modafinil has been tested in two placebo-controlled studies in SSRI partial responders. A pooled analysis suggested that modafinil is both effective and well-tolerated as augmentation therapy, particularly when patients continue to experience fatigue and excessive sleepiness (Fava et al. 2007).

Also dopamine agonists such as pramipexole demonstrated antidepressant activities in open clinical trials. Their usefulness, however, is limited as they may provoke sleep attacks and thus interfere with safety in daily life, for example, driving.

Two RCTs suggest that the addition of folic acid improves antidepressant action, but as monotherapy folate failed to separate from placebo in another RCT (Taylor et al. 2004).

Besides acting against agitation and sleep disturbances, benzodiazepines may have other augmentative effects on antidepressant treatment (Furukawa et al. 2000, Furukawa et al. 2001); however, their long-term use is clearly discouraged due to their inherent risk of addiction.

In some instances, for example, perimenopausal depression, augmentation with estrogen has been recommended based on small pilot studies. A randomized, double-blind pilot study tested antidepressant augmentation with the selective estrogen receptor modulator raloxifene, showing good tolerability of raloxifene and a nonsignificant trend to higher remission rates after 8 weeks (Grigoriadis et al. 2005). Clearly, more controlled studies with adequate sample sizes are demanded.

Summary
In summary, except for lithium and T₃, there is still a need for more controlled studies supporting pharmacological augmentation strategies. This area is receiving more scientific attention and ongoing studies like STAR*D or the Texas Medication Algorithm Project should supply further evidence for augmentation strategies in the near future, possibly leading to the development of evidence-based algorithms for treatment refractory patients.

Nonpharmacological Treatment Strategies

Electroconvulsive Therapy
ECT is defined as the induction of a series of generalized epileptic seizures for therapeutic purposes using brief-pulse stimulation techniques under anesthesia and muscle paralysis. The excellent therapeutic effectiveness of this method in the treatment of depression has been analysed in a variety of reviews and meta-analyses (Abrams 2002, Baghai et al. 2005, ECT review group 2003).

ECT as First Line Treatment
MDD accompanied by severe stupor as seen in melancholic, catatonic and/or psychotic depression may be a first line indication for ECT. If a rapid improvement is crucial for the patient, for example, in case of severe psychotic symptoms and/or high suicide risk, ECT should be considered earlier than other therapeutic options (American Psychiatric Association Committee on Electroconvulsive Therapy et al. 2001). In psychotic depression, remission rates for ECT of up to 90% have been reported, with relief experienced within 10–14 days (Petrides et al. 2001). The risk of suicide quickly declines under ECT, but the timely introduction of continuation treatments is essential to sustain the benefit (Kellner et al. 2005).

ECT also constitutes a first line alternative in conditions where antidepressants may be harmful, for example, during early pregnancy or the postpartum breast-feeding period, or in patients suffering from severe somatic diseases with the risk of worsening when exposed to antidepressants (Belles and Stoudemire 1998, Franco-Bronson 1996, Rothchild 1996).

ECT as Second Line Treatment
The most common use of ECT is after failure of medication to achieve remission or when several medication trials provoked side effects which were not tolerable. ECT combined with ongoing pharmacotherapy enhances response rates significantly (Baghai et al. 2006b). Other reasons for initiating ECT may include newly emerging somatic comorbidities limiting pharmacological treatment or worsening of depressive symptoms, including severe suicidality while on antidepressant pharmacotherapy (American Psychiatric Association Committee on Electroconvulsive Therapy et al. 2001).

Maintenance and Continuation ECT
The term continuation ECT (C-ECT) is predominantly used to characterize the maintenance treatment after successful treatment of the acute phase to prevent an early relapse into the index episode. It is sometimes distinguished from maintenance ECT (M-ECT) (Sartorius and Henn 2005) which should characterize prophylactic treatment preventing a recurrent episode of depression. As one merges into the other without sharp boundaries, only the term C-ECT is used here.

ECT is considered as an efficacious prophylactic tool in selected patients, although the scientific evidence for the use of ECT as a maintenance treatment is limited. One recent RCT found comparable efficacy for C-ECT and maintenance antidepressant pharmacotherapy (Kellner et al. 2006). Therefore, C-ECT could be considered in cases of relapse or recurrence of depressive symptoms when adequate pharmacological and psychological therapy failed.

When switching from acute treatment to C-ECT, the usual clinical procedure is to slowly prolong the treatment intervals and continue C-ECT for at least 6 months. A frequently used alternative strategy (the so-called cafeteria style) is to reestablish C-ECT treatment when the first signs of recurrence of depressive symptoms are reported (Abrams 2002, Fink et al. 1996). Regular weekly evaluations help to decide on an individual basis the adequate length of treatment-free intervals and when intervals need to be shortened.

Side Effects
According to the anesthetic used, the most frequent immediate side effects of ECT are headache, nausea, and vomiting. Due to predisposition or pharmacological interactions (e.g., lithium), prolongation of the action of muscle relaxants requiring longer assisted respiration may occur and on
rare occasions, prolonged seizures may need intervention with an anticonvulsant.

A typical side effect, more prominent in bilateral than in unilateral and in high than in low energy dose ECT, is transient cognitive impairment, consisting of short-term memory disturbances, a prolonged postictal reorientation period and memory disturbances including anterograde or retrograde amnesia (ECT review group 2003). Autobiographic long-term memory is very rarely affected (Lisanby et al. 2000). These effects are normally fully reversible; almost all patients report an amelioration of cognitive impairment after finishing the ECT treatment course (Devanand et al. 1991). However, some patients may experience lasting cognitive impairment, and more research is needed to characterize such patients a priori (Greenhalgh et al. 2005).

**Safety**

In general ECT is one of the best tolerated antidepressant therapies with low risk for severe complications, even lower than that associated with the use of TCAs. The mortality rate during ECT varies between 1:50,000 and 1:25,000 treatments (Abrams 2002, American Psychiatric Association Committee on Electroconvulsive Therapy et al. 2001). Recent improvements in ECT include the development of methods which maintain good therapeutic efficacy, but display better tolerability with respect to cognitive disturbances. Modified ECT techniques, including unilateral or bifrontal pulse wave stimulation, anesthesia with muscle relaxation, and sufficient oxygenation, reduce adverse events substantially (Ghazziuddin et al. 2000).

**Total or Partial Sleep Deprivation**

Total sleep deprivation is a nonpharmacological intervention, which exerts rapid antidepressant effects in about 60–70% of depressed patients who stayed awake for one night and the consecutive day (Benedetti et al. 2005, Wirz-Justice et al. 2005, Wu et al. 1990). Partial sleep deprivation means that patients get up between 1 and 2 AM and stay awake for the second half of the night and the consecutive day at least until 8 PM. This is as effective as total sleep deprivation and usually better accepted by depressed patients.

Early night sleep deprivation is ineffective in the treatment of depression (Wu et al. 1990).

The clinical usefulness of total sleep deprivation is limited since relapse is observed in most patients when returning to a normal sleep pattern (Wu and Bunney 1990), or even after a short nap on the next day (Riemann et al. 1993). Strategies for relapse prevention are the combination with medication, bright light therapy, or the serial administration of partial sleep deprivation up to twice (or three times) a week (Kuhs et al. 1998). As another nonpharmacological method, a “phase advance” of the sleep period after sleep deprivation can be used to prevent relapse in about 60% of responders (Berger et al. 1997) meaning that after one night of total sleep deprivation, the patients starts a partial sleep deprivation schedule from 5:00 PM to 12:00 midnight, which then is shifted back by 1 hour each day until a “normal” sleep time of 11:00 PM to 6:00 AM has been reached. This gives patients 7 hours of sleep per night and makes it easier to cope with the sleep deprivation procedure. Nevertheless, due to its labor intensive procedures and the fact that additional (pharmacological) treatments for relapse prevention are needed anyway, sleep deprivation is used predominantly as an augmentation strategy to speed up relief from depression.

**Bright Light Therapy (Phototherapy)**

In SADs, bright white light therapy is effective in the treatment of depressive symptoms (Wirz-Justice et al. 2005). Recent studies support the use of phototherapy as an efficacious adjunctive treatment in nonseasonal unipolar and bipolar depression (Martiny et al. 2005, Terman et al. 2005). More randomized controlled trials, however, are needed to evaluate the therapeutic impact of phototherapy on nonseasonal depression (Golden et al. 2005). Currently, phototherapy should be considered in SADs as one first line therapy, and it can be tried in other forms of depression as one of several augmentation strategies (Craft and Perna 2004).

**Psychosocial Treatments**

Several specific forms of psychotherapy have been developed for the treatment of depression, including CBT and IPT. In addition, various other forms of psychotherapy have been adapted for depression treatment. These include supportive psychotherapy, psychodynamic psychotherapy, and marital and family therapy.

In many psychiatric settings, combinations of psychotherapy and pharmacotherapy are provided. In this setting, supportive therapy is sometimes utilized (Winston et al. 2004). The psychiatrist focuses on establishing a positive therapeutic relationship with the patient. Ongoing education, collaboration with the patient, advice and encouragement are offered. The psychiatrist attempts to promote adherence to medication and other forms of therapy, combats hopelessness and helplessness, and remains alert for signs of suicidality. Such therapies are designed to address immediate needs for symptom reduction rather than primarily to achieve a deep level of psychological insight. Transference based interpretations are usually not a prominent part of such supportive therapy. Although often viewed as an eclectic form of therapy, some approaches to supportive therapy have been systematized (Novalis et al. 1993).

Combination pharmacotherapy and psychotherapy for depression has been studied but RCTs have not provided a clear answer to questions about when this is advantageous. In milder forms of depression, either pharmacotherapy or psychotherapy may be helpful; however, in more severe or complicated cases, combination therapy seems to confer a considerable advantage (Pampallona et al. 2004).

Marital and family conflicts are often significant factors in depression, in which cases, marital and family therapy may play a role in treatment. Several studies have shown effectiveness for marital therapy in relieving depressive symptoms as well as improving marital functioning (Beach 2003).

**CBT**

CBT for depression is typically a short-term course of individual therapy, ranging from eight to twelve sessions. In CBT, the patient and therapist form a collaborative relationship designed to address problems and symptoms pragmatically in the present (the “here and now”). Usually, delving deeply into childhood conflicts is not emphasized; the focus is on identifying and modifying distorted cognitions.
which are contributing to maintaining depressive symptoms and behaviors. The patient is helped to see the relationship between distorted, illogical thinking and depressed mood. CBT involves addressing the “negative cognitive triad”: negative views of self, one’s current world, and the future. Some type of behavioral activation strategy is often an important part of early therapy in CBT.

CBT is a structured therapy in which the therapist and patient develop explicit goals and an agenda for each session. Homework is typically given, which may involve reading assignments as well as monitoring thoughts, feelings, and behaviors, often using structured forms such as the “Daily Record of Dysfunctional Thoughts.” Homework is discussed in the subsequent session. If the patient is unable to complete the assignment, the process itself is discussed and viewed as a therapeutic opportunity. Homework assignments often embody behavioral activation and other behavioral techniques as well as cognitive monitoring. The patient is guided to learn to monitor and modify their own thinking processes, thereby acquiring a skill which will continue to help them after the formal therapy is completed. In some therapies, underlying, persistent beliefs known as schemas become a focus of treatment. These schemas involve deep seated beliefs about one’s self and the world, and are often inflexible. A typical schema involved in depression might be “I must please everyone” or “people would not like me if they knew what I’m really like.” Schemas can be addressed using many of the same techniques which are used to identify and modify negative automatic thoughts, but typically are much more difficult to change.

A number of studies have demonstrated the efficacy of CBT for major depression (Thase 1997). CBT is a relatively standardized form of treatment and, in addition, a computerized form has been developed (Wright and Small 2005).

Interpersonal Therapy
IPT is utilized primarily for outpatients with unipolar depression (Klerman et al. 1984). The focus is usually on four important interpersonal areas: interpersonal loss and grief (often following the loss or death of a loved one), role transitions involving difficulty adapting to changed life circumstances, interpersonal role disputes (usually with a loved one or close associate), and social deficits (limited social support networks). Interpersonal therapists believe that depression is maintained by problems in one or more of these four key areas. The therapy usually focuses on collaboratively identifying and correcting problems in one, or occasionally more than one, of these areas. The patient is encouraged to view depression as an illness involving problems to be solved rather than a personal weakness. Transference, exploration of the unconscious, dreams, defenses, and childhood experiences are usually not a part of IPT. The patient is educated about depression and its treatments, often including the use of medication. It is a pragmatic form of therapy that is designed to address symptoms in the present. It is usually a short-term therapy consisting of approximately 12–16 sessions.

IPT has been shown to be effective in clinical trials both alone and in combination with medication (de Mello et al. 2005). Continuation therapy with IPT has shown value in preventing relapse of depression (Frank 2007).

Psychodynamic Therapy
Psychodynamic psychotherapies are designed to address unconscious, intrapsychic conflicts using psychoanalytic techniques such as free association, analysis of defense mechanisms, and interpretation of transference. These therapies were not designed as a specific form of therapy for depression or overt symptom suppression. Psychodynamic therapies are usually unstructured and the therapist is typically less active than their counterparts in CBT or IPT, which may present a problem for a demoralized depressed patient. Unlike CBT or IPT, there is no authoritative manual or handbook. Moreover, there are a variety of approaches to psychodynamic psychotherapy, making generalizations difficult. Although Freud’s original contributions remain important, psychodynamic thinking has evolved enormously in recent decades, incorporating new insights from schools such as object relations and self psychology which may be applied to the treatment of depression. These observations focus on the nature of the self and its boundaries and relationships with others. Therapists may use these views in developing an empathic approach to the depressed patient very different to the traditional, reserved Freudian therapist. Psychodynamic therapy is usually open ended, but time limited approaches have been developed in recent decades. These brief dynamic therapies usually focus on current conflicts as manifestations of difficulty in early attachment and disruption of early object relations.

The efficacy of dynamic therapy has sometimes been controversial; however, recent studies have tended to show utility. Meta-analysis has suggested that longer durations of dynamic therapy may provide better outcomes than brief therapies (Leichsenring 2005, Leichsenring et al. 2006).

Psychotherapy in Primary Care Settings
As a trained psychotherapist may not always be available, it is an interesting question whether psychosocial treatment can be successfully delivered by general practitioners or community nurses. With a relative paucity of studies, evidence so far suggest that Problem-Solving Therapy for Primary Care (PST-PC) seems the most promising tool (Huibers et al. 2003). It typically involves an initial 60-minute session followed by five 30-minute sessions. PST-PC is largely based on the assumption that a range of life events or problems have a strong association with current psychological functioning (Nezu and Perri 1989). Besides MDD, PST-PC has also been shown to be an effective approach in minor depression and dysthymic disorder (Barrett et al. 2001). Techniques can be learned quite easily and PST-PC can be applied successfully by a trained community nurse (Wolf et al. 2007).
Another strategy for use in primary care settings is interpersonal counseling, developed by Klerman et al. (1987). It comprises a brief six-session intervention based on IPT, but designed to be administered by individuals who may not have mental health training, such as nurse practitioners. Especially in minor depression, IPC may be a useful and cost-effective tool (Weissman et al. 2000).

CBT, and the abbreviated form, are effective in primary care, but involves psychotherapeutic expertise which makes them impractical (Teasdale et al. 1984). Psychosocial counseling can take different forms, such as Rogerian psychotherapy, supportive psychotherapy, or psychoeducational techniques without supplemental interventions. In primary care settings, it may be effective in the short-term, but still lacks proven efficacy in the long run (Bower and Rowland 2006).

Recommendations
In general, empirically supported psychotherapies have demonstrated similar response and remission rates to pharmacotherapy for outpatients with depressive disorders, which, on average, may be less severely ill than inpatients. They treat mood and demoralization more quickly than neurovegetative symptoms of depression, the reverse of the pattern seen for most antidepressant medications. IPT and CBT also provide prophylaxis against relapse and recurrence when prescribed as less frequent (e.g., monthly) maintenance treatments (Frank et al. 2007).

However, the use of these psychotherapies clearly has its limitations. Some severely depressed patients may be too depleted to engage in psychotherapy effectively. They are also not intended to treat depression with psychotic features, nor as monotherapy for bipolar I depression (Frank et al. 2005, Miklowitz et al. 2003).

On the basis of their performance in controlled efficacy trials, IPT and CBT have already been included in some evidence-based professional and national treatment guidelines (Anderson et al. 2008, Karasu et al. 1993, National Institute for Health and Clinical Excellence 2004, Tylee 2006, van den Broek 2005).

For patients with chronic or severe depression, the combination of pharmacotherapy and one of these empirically validated psychotherapies may be preferable to monotherapy (Hollon et al. 2005). In a recent meta-analysis, the combined therapy outperformed psychotherapy, but only in moderate chronic depression, no differences were found in nonchronic depression (de Maat et al. 2007). Given health economics considerations, combined treatment may thus be reserved for patients with chronic, highly comorbid, severe depressions, or those at high suicide risk.

Issues in the Clinician–Patient Relationship
Throughout guidelines, there is a consensus that independent of the choice of the specific medical treatment intervention, general components of good psychiatric management, and psychotherapeutic support should be initiated and continued throughout the entire treatment (Bauer et al. 2002a, b). Elements of a good therapeutic alliance include the psychiatrist or physician taking full responsibility for diagnosis, conducting a physical examination, other investigations and explanation of the diagnosis and its consequences to the patient and relatives. The physician should listen to the patient’s complaints and communicate clearly, in an understandable manner. The physician should determine together with the patient a treatment plan and the appropriate treatment setting and, in case of outpatients, ensure regular visits. During acute phase treatment, weekly or biweekly visits are recommended; during the continuation phase and after syndromal recovery a frequency of once a month appears adequate (Bauer et al. 2002b). In the case of concurrent psychotherapy supplied by a psychotherapist, frequent communication between physician and therapist about the patient’s status should go without saying.

There should be regularly scheduled follow-up, reviewing the accuracy of diagnosis and treatment success, and a strategy to enhance adherence to medication (Anderson et al. 2008). Some additional aspects need special attention when treating depressed patients (adapted from Goodwin 2003):

- Patients and relatives should be educated about potential symptoms that may raise questions about the original diagnosis, for example, the emergence of (hypo)manic symptoms.
- Patients and relatives should be informed about the possibility of enhanced drive before the onset of antidepressant action in the initial antidepressant treatment phase possibly leading to an enhanced suicide risk.
- Patients should be made aware of stressors, the impact of sleep disturbance, the importance of regular patterns of activity and early signs of relapse.
- Patients should be informed about the poor outcome associated with alcohol and substance abuse and, if needed, given appropriate advice and offered treatment.
- Functional impairment should be evaluated and managed; patients and families should be given a realistic view about capacity to work and function within the family. Potential sources of psychosocial support in the community should be identified and the patient given help to contact them.

Special Factors Influencing Treatment
Although standardization and guidance by treatment algorithms is a desirable goal in order to ensure quality of care, neither the pharmacological nor psychological treatment of depression will ever become uniform in all patients. Different needs and risk factors need careful consideration across age groups and gender. Psychiatric comorbidities and personality traits may have a large confounding influence on outcomes. Psychiatric comorbidities, as outlined above, negatively impact on treatment outcomes and long-term prognosis, and need to be treated simultaneously with the same effort as the depressive episode.

Medical comorbidity will affect both treatment responsiveness of depressive syndromes and the choice of medication, as both pharmacokinetic interactions with somatic medication and potential safety risks due to organ dysfunction have to be observed (see Section, “Depressive Disorders with Comorbid General Medical Conditions”).

It goes almost without saying that enduring psychological factors, for example, low self-esteem, lack of knowledge about the illness and hence an inappropriate concept of the illness, as well as an unfavorable social environment may
not only delay recovery, but also be risk factors for relapses. Thus, psychological counseling on an individual basis, psychoeducation, and intense social support are often needed for achieving treatment success.

Clinical Vignette 1

**Depression Dominated by Somatic Symptoms**

Mrs. D is a 62-year-old former teacher, living single, who retired from work 6 months ago. She presented to her GP complaining about loss of appetite, constipation, abdominal cramps, and a general feeling of weakness and loss of energy. Abdominal sonography and an abdominal CT scan were without pathological findings, but there were moderate signs of dehydration with an increase in creatinine and hematocrit as well as low serum iron and serum ferritin. She was prescribed a combined iron sulphate-folic acid preparation and advised to drink at least 1.5 L/day. No improvement in symptoms was observed after 1 month. Mrs. D now also complained of an increasing loss of pleasure. She was referred to a psychiatrist for a second opinion. At presentation she also reported low self-esteem after retirement and difficulties structuring her daily routine also she didn’t feel challenged by it. Diagnosis of a MDD was made and Mrs. D was started on fluoxetine 20 mg/day. She was sent to a CBT therapist. Her low self-esteem after retirement and consecutive thoughts of being now worthless became the focus of the CBT. After having 12 sessions of CBT and fluoxetine at final dose of 40 mg for 8 weeks she started to improve slowly but constantly and reached full recovery after 3 months of treatment. For the next 2 years, CBT was continued on low frequency with one session per month and she continued to take fluoxetine for another year before it was tapered out over a 6-month period.

Clinical Vignette 2

**Treatment Refractory Depression**

Mr. J is a 51-year-old, married tax accountant. Soon after his 50th birthday, he experienced a temporary financial shortage and was not able to pay all bills in time. Thereafter he developed an increasing feeling of worthlessness, constant thoughts of guilt and shame, accompanied by hyposomnia and weight loss. He reported to his GP where diagnosis of an MDD was established. Mr. J was started on citalopram 20 mg for 2 weeks, then 40 mg for another 2 weeks and finally 60 mg/day but no improvement was observed after 8 weeks. Careful questioning by the GP revealed that he was now also suffering from increasing thoughts of death and as a consequence he was referred to a psychiatrist. The psychiatrist confirmed the diagnosis of MDD and switched citalopram to venlafaxine with a maximum dose of 225 mg after 4 weeks of treatment. However, Mr. J was not able to tolerate the high dose of venlafaxine; he developed increasing psychomotor agitation but showed no improvement of the depressive syndrome. In parallel with the switch of medication, CBT was initiated but Mr. J felt overstrained by the therapy. Psychotherapy was cut back to an unchallenging, supportive level. Due to lack of improvement and side effects, venlafaxine was then tapered and mirtazapine started. Initially, mirtazapine lead to an improvement of sleep and a decrease of psychomotor agitation. But even with 60 mg of mirtazapine after 3 weeks the other depressive symptoms remained and thoughts of death became more intense leading to Mr. J’s admission to in-patient care. In hospital mirtazapine was reduced to 45 mg and lithium augmentation was started after 2 weeks a lithium serum level of 1.0 mmol/L was achieved, and the first signs of improvement were observed. With the constant medication of the lithium and mirtazapine, reduced to 45 mg/day, Mr. J was able to restart on CBT after 4 weeks and to gain profit from psychotherapy. Improvement continued and 3 months later Mr. J achieved full recovery. Due to the severity of the depressed episode, Mr. J and his psychiatrist decided on long-term prophylactic treatment with lithium and regular booster sessions of CBT.

Acknowledgments

This chapter was compiled largely in parallel with the CINP taskforce review “Antidepressant Medications and Other Treatments of Depressive Disorders A CINP Task Force Report Based on a Review of Evidence” (Sartorius et al. 2007). By using large parts of the material originally collected for this task force review, we are thankful to the members of and advisors to this taskforce who indirectly gave also their input to this chapter. We are also specially thankful to Cornelius Schiele who contributed extensively to the Section, “Etiology and Pathophysiology”.

End Notes

1 Within DSM-IV recurrent brief depression can only be diagnosed as sub-threshold major depressive disorder (MDD) although it is included in the research appendix. Within ICD-10 it is a diagnostic category of recurrent depressive disorder. The combination of severe depressive disorders and recurrent brief depression is sometimes also called “combined depression” (Pezawas et al. 2001).

2 Reboxetine up to now is marketed in Europe, but not in the United States.

3 In addition antidepressants do not have a market value to drug misusers, an authentic measure of abuse potential.

4 Also antipsychotics such as clozapine or olanzapine (Duggal et al. 2004) used in augmentation therapies may cause leukopenia culminating to agranulocytosis.

5 Comment on paroxetine: in case of acute angle-closure (closed-angle, narrow-angle) glaucoma contraindicated due to more anticholinergic side effects in comparison to other SSRIs (Bennett and Wyllie 1999).

6 TCAs are available as oral and intravenous (i.v.) applicable medication. There is no scientific evidence for a differential efficacy profile of both pharmaceutical forms.

7 In addition to the serotonin reuptake inhibiting properties escitalopram binds at the allosteric site on the serotonin transporter. The definition of a new class of SSRIs has been suggested (Allosteric Serotonin Reuptake Inhibitors (ASRI)).

8 Not yet available, currently under review by European authorities (EMEA).

9 Selegiline in some countries has been approved only as a drug against Parkinson’s disease, not as an antidepressant.

10 The use of pirisodol is limited to Russia and other eastern countries of the same geographical region. In the Russian literature it can be found under other names, such as pirilindol, pyrazidol, pirazidol or pirazidolum (for review: see Mosolov (1998)).

11 Nefazodone has been withdrawn from the market in some countries.

12 Melitracen has activating properties in low dosages and is predominantly used in Asian countries in a combined formulation (deanxit) with the antipsychotic drug fluoxetine.

13 Different dosages are used in different countries (Patten et al. 2005, Sartorius 1986). For some populations, e.g., Japanese patients, the above mentioned dose recommendations are usually too high. Otherwise the definition of standard doses according to approval studies for authori-
treatment costs. Also indication adjusted dose recommendations may be of importance. The indications for which antidepressant medications are used vary among countries.

14 Recommended starting dose in the US 40mg, in Europe 60 mg.

15 The sorting order represents grading from common and unimportant to more severe, but predominantly rare side effects.

16 Syndrome of inadequate secretion of antiidiuretic hormone, possibly resulting in hyponatremia and generalized epileptic convulsions.

17 Due to decreased platelet concentration or diminished platelet aggregation.

Disorders (continued)
Introduction

Historical Background
Mania and depression have been recognized as far back as Western classical antiquity, and recognizable descriptions of bipolar (manic–depressive) disorder can be found in the writings of Galen’s contemporary, Aretaeus of Cappadocia (c. 150–200 CE) (Porter 2002). Importantly, the debate regarding biological versus psychosocial etiologies of this and other mental illnesses can be traced forward from antiquity to the present day with impressive consistency: though the specific attributions and colorings may change, the tension between these two alternatives appears to be a consistent feature of Western thought about mental illness (Porter 2002, 2004).

The modern age of study of manic–depressive disorder can be considered to have begun with Emil Kraepelin, whose treatise Manic–Depressive Insanity and Paranoia (Kraepelin 1899, Kraepelin 1989, Berrios and Hauser 1988) is a classic in terms of both the importance of its scientific insights and the lucidity of its prose. Notably, this seminal work emphasized clinical description rather than pathogenesis, and emphasized both cross-sectional and longitudinal data. Kraepelin observed that patients who had symptoms of psychosis were of two main types: those whose illness followed a progressive downhill course and those whose illness remitted and recurred, frequently with return to their normal interepisode baseline. The former illness he termed dementia praecox, “early dementia,” which we now call schizophrenia. The latter he called manic–depressive psychosis. This latter group included almost all severe mood disorders, grouping together persons with severe depressive episodes regardless of whether they experienced mania as well. Thus, he utilized not only cross-sectional data (the occurrence of mood episodes) but also longitudinal data (the tendency of mood episodes to remit and recur) to separate mood disorders from schizophrenia.

Later, Leonhard and Berman (1957) proposed the distinction between manic–depressive, or bipolar, disorder and pure depressive disorder, which has come to be called unipolar depression. Phenomenologically, Leonhard based this distinction on the occurrence of manic episodes in the former disorder but not in the latter, and supported this distinction by the observation that mania tended to occur more frequently in family members of patients with manic–depressive rather than unipolar disorder. This is an example of corroborating purely phenomenological distinctions with other types of empirical evidence, which was later codified in Robins and Guze’s (1970) classic article on the definition of schizophrenia, which eventually served as the basis for evaluating most of the evidence for mood disorder validation for DSM-IV-TR.

This categorical approach to diagnosis, which clearly demarcates manic–depressive disorder from schizophrenia on the one hand and from unipolar depression on the other, is most successful when classic cases are considered. In reality,
However, many boundary cases exist in which features of more than one syndrome exist and clear categorization is not possible. Recognizing this reality, Bleuler’s classic *Textbook of Psychiatry* (Bleuler and Brill 1924) proposed that manic–depressive disorder and schizophrenia lie on a continuum that has no sharp border, with patients often exhibiting characteristics of both syndromes and evolving a course midway between the two. This presentation is indeed not uncommon and has been recognized in major diagnostic classification schemata as schizoaffective disorder (Levitt and Tsuang 1988, Blacker and Tsuang 1992). As discussed below, modern psychiatric genetics also provides some support for Bleuler’s continuum approach (e.g., Craddock and Owen 2005).

The most recent roots of the atheoretical, phenomenological approach to diagnosis in the current DSM system lie in the St. Louis or Feighner criteria (Feighner et al. 1972), which specified explicit phenomenological criteria for the identification of various psychiatric disorders. The St. Louis criteria and the closely related Research Diagnostic Criteria (Spitzer et al. 1978) served as the diagnostic systems for most clinical psychiatric research in the 1970s and early 1980s, providing a common language for description of patients among investigators and increasing comparability of diagnostic samples across various sites. This phenomenological “technology” diffused into clinical practice and was codified for clinical use by the third edition of the DSM and its revision (American Psychiatric Association 1980, 1987). Currently, the DSM-IV-TR and the closely related *International Statistical Classification of Diseases and Related Health Problems*, 10th Revision (ICD-10) (World Health Organization 1994) serve as the basis for the diagnosis of manic–depressive disorder both in clinical practice and in psychiatric research, although long-term psychiatric studies begun under the Research Diagnostic Criteria have continued to use that schema, which is fairly comparable (Williams and Spitzer 1982).

**A “Bipolar” Disorder?**

In the first edition (Tasman et al. 1997), this chapter was entitled “Bipolar Disorders,” yet beginning with the second edition the older term “manic–depressive disorder” has been included. Why?

Classically, mania has been considered to be the opposite of depression: manic individuals were said to be cheery, optimistic, and self-confident—hence the name bipolar disorder. However, in most descriptive studies, substantial proportions of hypomanic and manic patients actually exhibit dysphoric symptoms (e.g., Bauer et al. 1991, 1994c), while those with depressive episodes frequently exhibit manic symptoms (e.g., Benazzi 2004). In fact, admixtures of manic and depressive symptoms may be the modal mood state in unselected populations of individuals with this illness (Bauer et al. 2005b).

Further evidence that (hypo)mania is not the polar opposite of depression comes from investigation of self-reported quality of life in the various mood states of manic–depressive disorder (e.g., Vojta et al. 2001, Zhang et al. 2006). Although classically thought to be a desirable state, patients with mania or hypomania rate their preference for that state as equal to or less than their preference for euthymia, with depression and mixed states being rated less preferable.

Thus the term manic–depressive is less misleading than “bipolar,” which implies that the two characteristic mood states are somehow polar opposites (see Section “Phenomenology”). This chapter therefore refers to the disorder by its older, but more accurate, name.

**Diagnosis**

**Definition and Diagnostic Features**

The phenomenological data for the diagnosis of manic–depressive disorder depend on both *cross-sectional* and *longitudinal* data. “Cross-sectional” refers to descriptive aspects of a syndrome that occur at a particular point in time, such as the number and type of symptoms that occur during an episode of depression. “Longitudinal” refers to the course of symptoms over time, such as the timing, duration, and recurrence of depressive episodes. It is not infrequent that diagnostic errors occur when longitudinal data are neglected as the psychiatrist focuses solely on cross-sectional presentation: “This must be manic–depressive disorder because the patient appears manic at the present time,” or “this cannot be manic–depressive disorder because the patient is depressed now.”

**Episodes as the Basis for Diagnosis of Manic–Depressive Disorder**

The DSM-based definition of manic–depressive disorder is built on the identification of individual mood *episodes* (Table 67–1). DSM-IV-TR criteria for individual mood episodes are summarized below for manic, mixed, and hypomanic episodes; criteria for major depressive episodes can be found in Chapter 66. Criteria for these episodes are reviewed in greater detail in the subsequent section on diagnosis. Most individuals with manic–depressive disorder have major depressive as well as mania or hypomanic episodes (Winokur et al. 1969, Solomon et al. 2003). Those who experience manic episodes are diagnosed with manic–depressive or bipolar type I disorder, and those with major depressive

and hypomanic (milder manic) episodes are diagnosed with manic–depressive or bipolar type II disorder.

Not surprisingly, most data regarding manic–depressive disorder come from the study of the more severe end of the spectrum, primarily type I disorder. Throughout this chapter, data on manic–depressive disorder derive from studies of type I disorder unless otherwise noted. DSM-IV-TR is the first version of the DSM series to include a specific category for type II disorder. Previously, persons with depressive and hypomanic episodes were grouped under the broad “bipolar disorder not otherwise specified,” which included a variety of unusual presentations. On the basis of evidence reviewed by Dunner (1993), type II disorder was given separate categorical status.

This separation of type II from both type I and major depressive disorders is supported by several types of evidence. For instance, type II disorder occurs more frequently in families of persons with type II in comparison to families of persons with type I or major depressive disorder (Fieve et al. 1984, Coryell et al. 1984, Endicott et al. 1985). Study of the course over time of type II disorder indicated that persons with hypomania tended to have recurrent hypomanic episodes and did not convert into type I by developing mania (Coryell et al. 1995). In addition, persons with type II disorder may have more episodes over time than persons with type I (Dunner 1993). However, biological differences between these manic–depressive types have not been reliably demonstrated (Dunner 1993).

Nonetheless, as summarized in Section “Clinical Outcome,” it should not be construed that type II disorder

Manic Episode
A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary).
B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:

(1) inflated self-esteem or grandiosity
(2) decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
(3) more talkative than usual or pressure to keep talking
(4) flight of ideas or subjective experience that thoughts are racing
(5) distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
(6) increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
(7) excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
C. The symptoms do not meet criteria for a mixed episode.
D. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

Note: Manic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of manic–depressive I disorder.

Mixed Episode
A. The criteria are met both for a manic episode and for a major depressive episode (except for duration) nearly every day during at least a 1-week period.
B. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
C. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

Note: Mixed-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of manic–depressive I disorder.

is in all respects milder than type I, although hypomania is by definition less severe than mania. Specifically, the social and occupational function and quality of life for persons with type II disorder are similar to those for persons with type I disorder.

Persons who experience subsyndromal manic-depressive mood fluctuations over an extended period without major mood episodes are diagnosed with cyclothymic disorder. Much less is known about this milder disorder because afflicted persons present for medical attention less frequently than those with full-blown manic-depressive disorder. Cyclothymic disorder has been considered at various times a temperament, a personality disorder, and a disorder at the milder end of the manic-depressive spectrum (Akiskal 1981). Available data clearly indicate that cyclothymic disorder is related to the more severe manic-depressive disorders (Akiskal et al. 1977, Goodwin and Jamison 1990). However, it is not clear to what degree such categorical disorders may be related to underlying dimensional characteristics such as temperament (Akiskal and Akiskal 2005). It is also not clear to what degree defining milder and milder categories for the disorder (e.g., “bipolar type 2.5” (Akiskal et al. 2003), “bipolar type 3” (Akiskal and Akiskal 1988), etc.) will have clinical utility.

**Phenomenology**

Mood episodes are discrete periods of altered feeling, thought, and behavior. Typically they have a distinct onset and offset, beginning over days or weeks and eventually

---

**DSM-IV-TR Criteria**

**Hypomanic Episode**

A. A distinct period of persistently elevated, expansive, or irritable mood, lasting throughout at least 4 days, that is clearly different from the usual nondepressed mood.

B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:

1. Inflated self-esteem or grandiosity
2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
3. More talkative than usual or pressure to keep talking
4. Flight of ideas or subjective experience that thoughts are racing
5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., the person engages in unrestrained buying sprees, sexual indiscretions, or foolish business investments)

C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the person when not symptomatic.

D. The disturbance in mood and the change in functioning are observable by others.

E. The episode is not severe enough to cause marked impairment in social or occupational functioning, or to necessitate hospitalization, and there are no psychotic features.

F. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

*Note:* Hypomanic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of manic-depressive II disorder.

---

**Cyclothymic Disorder**

A. For at least 2 years, the presence of numerous periods with hypomanic symptoms and numerous periods with depressive symptoms that do not meet criteria for a major depressive episode.

*Note:* In children and adolescents, the duration must be at least 1 year.

B. During the above 2-year period (1 year in children and adolescents), the person has not been without the symptoms in criterion A for more than 2 months at a time.

C. No major depressive episode, manic episode, or mixed episode has been present during the first 2 years of the disturbance.

D. The symptoms in criterion A are not better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).

F. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

---

ending gradually after several weeks or months. As noted earlier, manic–depressive disorder is defined by the occurrence of depressive plus manic, hypomanic, or mixed episodes, or the occurrence of only manic or mixed episodes.

Major depressive episodes are defined by discrete periods of depressed or blue mood or loss of interest or pleasure in life that typically endures for weeks but must last for at least 2 weeks (see Chapter 66). These symptoms are often accompanied by changes in increase or decrease in sleep or appetite, decreased energy, and impaired cognition. Depressive episodes in manic–depressive disorder are indistinguishable from those in major depressive disorder (e.g., Abrams and Taylor 1980, Moller et al. 2001). About 75% of persons with manic–depressive disorder experience depressive episodes characterized by decreased sleep and appetite, while about 25% experience more “atypical” symptoms of increased sleep and appetite, rates that are indistinguishable from those in unipolar depression (Robertson et al. 1996, Posternak and Zimmerman 2002). Thus with regard to depressive episodes, the differential diagnosis between major depressive and manic–depressive disorders is made by longitudinal course not by cross-sectional symptom analysis. A diagnostic decision tree for manic–depressive disorder is given in Figure 67–1.

Manic episodes are defined by discrete periods of abnormally elevated, expansive, or irritable mood accompanied by marked impairment in judgment and social and occupational function. These symptoms are frequently accompanied by unrealistic grandiosity, excess energy, and increases in goal-directed activity that frequently have a high potential for damaging consequences.

Hypomanic and manic symptoms may be identical, but hypomanic episodes are less severe. A person is “promoted” from hypomania to mania (type II to type I) by the presence of one of three features: psychosis during the episode, sufficient severity to warrant hospitalization, or marked social or occupational role impairment. This is an imperfect set of criteria, however, because the phenomenologic differentiation between hypomania and mania is not as cut-and-dried as one would hope. Of the three characteristics by which one is “promoted” from hypomania to mania, only the presence of psychosis is firmly grounded in the characteristics of the individual. The other two characteristics, marked social or occupational role impairment or hospitalization, clearly have components that are primarily external to the individual. If, for instance, one individual has relatively mild manic symptoms but is living with a family who is unable to tolerate the behavior, she/he is more likely to be hospitalized. Similarly, the comorbid presence of a severe disorder is more likely to result in hospitalization and a “promotion” from type II to type I disorder. Contrarily,
limited insurance benefits, or a more tolerant family increase the probability that a manic syndrome of a given severity will be managed without hospitalization and thus be diagnosed as “hypomania” rather than “mania.” Overall, however, there is evidence that type II and type I manic–depressive disorders are separable (see Section “Episodes as the Basis for Diagnosis of Manic–Depressive Disorder”), though whether these represent separate categories versus different positions or a single continuum remains unclear.

Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria
The ICD-10 item set for a manic episode contains nine items, in contrast to the seven items in the DSM-IV-TR criteria set, the two additional items being marked sexual energy or indiscretions and loss of normal social inhibitions. However, the number of items required by ICD-10 Diagnostic Criteria for Research remains the same as the number in DSM-IV-TR (i.e., three items if mood is euphoric, four items if mood is irritable), which is likely to result in a more inclusive diagnosis of a manic episode in ICD-10. Furthermore, the duration of mixed episodes differs, with DSM-IV-TR requiring a duration of 1 week (as is the case for a manic episode), whereas the ICD-10 Diagnostic Criteria for Research require a duration of at least 2 weeks.

The criteria sets for hypomanic episode differ as well. The ICD-10 Diagnostic Criteria for Research contain several additional items (increased sexual energy and increased sociability) and does not include the DSM-IV-TR items inflated self-esteem and flight of ideas. Furthermore, ICD-10 does not require that the change in mood be observed by others.

Regarding the definition of type I disorder, in addition to differences in the diagnostic criteria for a manic and major depressive episode, the ICD-10 definition of “Bipolar Affective Disorder” (i.e., any combination of hypomanic, manic, or mixed with depressive episodes) does not distinguish between type I and type II disorder (i.e., cases of DSM-IV-TR Bipolar II Disorder are diagnosed as Bipolar Affective Disorder in ICD-10). However, ICD-10 Diagnostic Criteria for Research do include a diagnostic criteria set for type II in its appendix that is identical to the criteria set in DSM-IV-TR.

For cyclothymic disorder, the ICD-10 Diagnostic Criteria for Research provides list of symptoms that must be associated with the periods of depressed mood and hypomania, which differ from the ICD-10 item sets for dysthymic disorder and hypomania. In contrast, the DSM-IV-TR definition of cyclothymic disorder utilizes the same criteria for hypomania.

Screening for Manic–Depressive Disorder
Since the last edition of this chapter, two brief instruments for screening for manic–depressive disorder have been developed and subjected to psychometric analysis. The Mood Disorders Questionnaire (Hirschfeld et al. 2000) consists of a yes/no checklist based on DSM-IV-TR criteria for mania. The second screener, the Bipolar Spectrum Diagnostic Scale (Ghaemi et al. 2005), consists of a text paragraph describing various symptoms that might occur during (hypo)mania followed by a single item with four choices: “This story fits me very well, or almost perfectly….This story fits me fairly well…. This story fits me to some degree, but not in most respects…. This story doesn’t really describe me at all.”

The sensitivity and specificity of the MDQ have been reported as, respectively, 0.28–0.73 and 0.67–0.90, and for the BSDS, respectively, 0.75 and 0.79 (Phelps and Ghaemi, 2006). The developers of one of these scales cogently conclude that each of these instruments could be useful as screening tools, but are not useful for diagnostic confirmation (Phelps and Ghaemi 2006). That is, a positive response merits further diagnostic evaluation but does not mean the individual has a manic–depressive spectrum disorder (low positive predictive value), while a negative response makes it unlikely that the individual has such a disorder (high negative predictive value).

Additional Features: Psychosis and Rapid Cycling
Psychosis is an episode modifier and can occur in either depression or mania. If psychotic symptoms are limited to the major mood episode, the individual is considered to have manic–depressive disorder with psychotic features. On the other hand, if psychotic symptoms endure significantly into periods of normal mood, the diagnosis of schizoaffective disorder is made. For the formal DSM definition, 2 weeks of psychotic symptoms during normal mood is sufficient to convert a diagnosis of manic–depressive or major depressive disorder into schizoaffective disorder, because it is thought that such persons have a clinical course midway between individuals with mood disorders or schizophrenia. However, this cut-off point is fairly arbitrary, and its validity is not well established (Levitt and Tsuang 1988, Blacker and Tsuang 1992).

Rapid-Cycling Specifier
Specify if:
With rapid cycling (can be applied to manic–depressive I disorder or manic–depressive II disorder). At least four episodes of a mood disturbance in the previous 12 months that meet criteria for a major depressive, manic, mixed, or hypomanic episode.

Note: Episodes are demarcated by either partial or full remission for at least 2 months or a switch to an episode of opposite polarity (e.g., major depressive episode to manic episode).

or depressed) in 12 months as the cut-point (e.g., Bauer et al. 1994a), not all studies support a firm cut-off (e.g., Kupka et al. 2003), and here also it is likely that the phenomenon is part of a continuum rather than a set of discrete categories. Various studies have identified individuals with mood episodes of very brief, even 1 day, duration; such “ultra” or “truncated” rapid cycling shares many clinical features with DSM-defined rapid cycling, and in fact the vast majority of such individuals at some time also meet DSM criteria for rapid cycling (Bauer et al. 1994a).

Rapid cycling is of significance because it predicts a relatively poorer outcome and worse response to lithium and other treatments (e.g., Bauer and Whybrow 1993, Bauer et al. 1994b, Maj et al. 1994). Although rapid cycling was at one time considered by some to be an “end stage” of the disorder, empirical evidence indicates that it may have its onset at any time during the disorder (Bauer and Whybrow 1991, 1993, Bauer et al. 1994a) and may come and go during the course of illness (Coryell et al. 1992). Several specific risk factors may be associated with rapid cycling, each of which may give clues to its pathophysiology. These include female gender, antidepressant use, and prior or current hypothyroidism (Bauer and Whybrow 1993, Bauer et al. 1994b).

Assessment

Rationale for the Medical Assessment of Individuals with Manic–Depressive Disorder

Although the diagnosis of manic–depressive disorder is made on the basis of phenomenology, there are several reasons to conduct a thorough medical history and physical examination. First, there are several general medical or substance-related causes of manic depression that, if treated, may lead to the resolution of the mood episode. Second, medical evaluation is necessary before starting several types of medications used in the treatment of manic–depressive disorder. Third, ongoing medical assessment is required for tracking medication-induced side effects of several types of medications. Finally, for many patients with psychiatric illnesses, particularly chronic or severe illnesses, their first contact with medical care as an adult may be during the psychiatric interview—often under inpatient or even involuntary conditions. Because psychiatric illness is clearly not protective against medical illnesses, and since even common general medical illnesses may never have been screened for in the past, a thorough medical history and physical examination are necessary parts of the basic care of patients.

Many textbooks recommend a history, physical examination, and laboratory testing for the routine evaluation of persons with mood disorders. Although the history and physical examination are commonsense medical procedures, the use of laboratory testing, particularly routine screening batteries, is supported by few data (Bauer et al. 1993, Agency for Health Care Policy and Research 1993). For instance, using screening for thyroid abnormalities in individuals presenting with depressed mood as an example, Briggs et al. (1993) found no evidence that the prevalence of thyroid disorders among ambulatory patients with depression exceeds that in the general population. It has therefore been recommended to follow standard screening recommendations for the general population in individuals with depression (Agency for Health Care Policy and Research 1993).

The overall approach to evaluating persons with manic–depressive disorder for medical problems may be summarized as follows:

- Persons with psychiatric disorders, including manic–depressive disorder, should have regular screening for disease detection and health maintenance purposes as recommended for the general population.
- However, it should also be kept in mind that individuals with manic–depressive disorder, by virtue of having an often severe and disabling behavioral disorder, are less likely than the general population to have had adequate medical screening and treatment.
- Thus, special care must be made to ensure that health problems are not overlooked and that appropriate treatment or referral is effected.

If results of the history or physical examination reveal abnormalities, or if the psychiatric illness or treatment is associated with particular general medical conditions, more intensive testing is warranted. Examples of this latter are the use of lithium or some second generation antipsychotics, which are associated with, respectively, increased rates of thyroid and renal abnormalities or increased rates of obesity and type II diabetes.

Medical Precipitants of Manic or Depressive Symptoms

Krauthammer and Klerman (1978) conceptualized secondary mania as mania occurring close on the heels of a specific known physiological insult, such as general medical illness or exposure to mania-inducing pharmacological agents. Most medical illnesses that affect brain function have been described in case reports or small case series to cause one or another psychiatric syndrome (Table 67–2), although none can be considered specific risk factors. Case reports or case series that propose that a putative causative medical illness is associated with manic–depressive disorder must be interpreted with caution. For instance, Josephson and MacKenzie (1979) described an association between hyperthyroidism and mania. However, almost all of these patients had additional factors that most likely contributed to the development of mania, such as a preexisting mood disorder due to a general medical condition or a prior history of mood disorders. Too much thyroid hormone in and of itself is not likely to cause mania (Bierwaltes and Ruff 1958). On the other hand, administration of medications has been

observed frequently in clinical practice to be associated with the onset of mania, particularly in patients with preexisting depression. Such medications are listed in Table 67–3. Depressive symptoms may also be associated with certain medical conditions (Table 67–4) and medications or drugs (Table 67–5).

Some controversies have been hotly debated, particularly regarding the role of antidepressants in causing mania and rapid cycling (Prien et al. 1973b, Lewis and Winokur 1982, Wehr et al. 1993, Altshuler et al. 1995a; see also Section “Balancing Risks and Benefits of Antidepressant Treatment”). Of particular importance to psychiatric practice, all efficacious antidepressant treatments have been suspected to cause the induction of mania, with the exception of lithium, lamotrigine, and psychotherapy. Occasionally when a new antidepressant is developed, hope is raised that it will be the agent that will not induce mania. Clinical experience has not borne out these early hopes. This caveat for antidepressants also includes nonpharmacological antidepressants such as light and electroconvulsive therapy (ECT). The latter effect is paradoxical, as ECT is also used successfully to treat mania.

### Tracking Manic and Depressive Symptoms with Rating Scales

A plethora of rating scales is available for assessing manic and depressive symptoms, and associated features such as psychosis, functional status, and healthcare costs. For general information, the reader is referred to the compilation of rating scales by the APA (American Psychiatric Association Task Force for the Handbook of Psychiatric Measures 2000). For clinical usage, clinicians rating scales in general use for depression (see Chapter 66) can also be used for depressive episodes in manic–depressive disorder. Most share the shortcoming of tending to underrate hypersomnia, hyperphagia, and weight gain, “atypical” features that are common in manic–depressive disorder. Among mania scales, the Young Mania Rating Scale (Young et al. 1978, 1983) is well validated on outpatients as well as inpatients, and for hypomanic as well as manic episodes.

Self-report scales have the advantage of being brief (typically 5 minutes) and amenable to frequent, even daily, usage without undue burden. However, it is apparent that the simple single analog mood rating once widely used (“best” to “worst” mood) is of limited utility because of the high frequency of mixed symptoms (see Section “A ‘Bipolar’ Disorder?”).

With the caveats noted regarding interview-based assessment of depression in this disorder, self-report instruments for unipolar depression can reasonably be used in manic–depressive disorder as well. Self-reports
for (hypo)manic symptoms have also been developed, and validation data indicate that insight sufficient for self-rating is preserved in most individuals in such episodes (e.g., Bauer et al. 1991, Sugar et al. 1992, Altman et al. 1997). Self-rating scales for (hypo)mania include the following: the Internal State Scale (ISS; Bauer et al. 1991, Glick et al. 2003), which also includes a rubric for diagnosing (hypo)manic, depressive, and mixed episodes as well as a depression symptom severity measure; the Self-Report Manic Inventory (Sugar et al. 1992); and the Altman Self-Rating Mania Scale (ASRS; Altman et al. 1997). The ASRS (Alvarez Mas et al. 2005) is available in Spanish, and the ISS is available in Castilian, Mexican, Caribbean Spanish, French, and German.

**Epidemiology**

Epidemiological studies assess the incidence (onset frequency), prevalence (overall population load), and related characteristics in large samples of persons who are typically not preselected on the basis of presentation for clinical care. These studies are a valuable complement to clinic-based studies for several reasons. First, epidemiological studies avoid biases inherent in studying clinic-based samples. For example, clinical populations may underrepresent the milder (or most severe) variants of a disorder; further, willingness to request clinical care may be associated with sample characteristics that bias the sample in unknown ways. In addition, epidemiological studies may be helpful in determining overall population load for a particular disorder, which can be helpful in planning health services. On the other hand, the large sample size and required methodology for most epidemiological studies limit the extent to which any individual subject can be assessed.

Estimates of the lifetime risk for manic–depressive I disorder from epidemiological studies have ranged from 0.2 to 0.9% (Fremming 1951, Parsons 1965, James and Chapman 1975, Weissman and Myers 1978, Helgason 1979). The Epidemiological Catchment Area (ECA) study found a lifetime prevalence rate of 1.2% for combined type I and type II variants (Weissman et al. 1988); this agrees closely with the earlier study of Weissman and Myers (1978), which found 0.6% prevalence for each of the types individually. Little is known regarding the prevalence of cyclothymic disorder. The lifetime community prevalence rate of “bipolar spectrum” disorders has been estimated to be as high as 6%, based on at least two hypomanic symptoms lasting less than 1 week (Judd and Akiskal 2003).

Unlike major depressive disorder, manic–depressive disorder has an approximately equal gender distribution (Weissman et al. 1988). Few consistent data are available regarding differences in prevalence across ethnic, cultural, or rural–urban settings within the US, while there are some cross-national differences in mania (Sherazi et al. 2006). However, one of the more intriguing puzzles is the tendency of manic–depressive disorder to occur in higher socioeconomic strata than schizophrenia, which tends to aggregate in lower socioeconomic strata. Several theories have been advanced to explain this phenomenon (Goodwin and Jamison 1990, pp. 169–174), and some have questioned this association (Sherazi et al. 2006); however, several issues are clear. First, the finding is most likely not exclusively due to diagnostic bias (i.e., overdiagnosing persons of lower socioeconomic class with schizophrenia more frequently than manic–depressive disorder and the converse in persons of higher socioeconomic class). Second, the upward socioeconomic “drift” is not due to highly impaired patients “dragged” upward by higher functioning family members who are normal or who have adaptive subsyndromal manic–depressive spectrum characteristics; rather, patients themselves, at least those with type II disorder, are in many cases highly successful and occupy higher socioeconomic levels (Coryell et al. 1989a). Third, the findings are not limited to the US but have been replicated in European samples as well (Lenzi et al. 1993).

Of particular interest in regard to the epidemiology of manic–depressive disorder is that the incidence of manic–depressive disorder (and depressive disorders) appears to have increased since the 1940s (Gershon et al. 1987). Reasons for this are not clear, although environmental factors, either physiological or psychosocial, may be responsible. For instance, exposure to increasingly severe social stressors, or the breakdown of cultural supports that may buffer stresses, may contribute; increases in exposure to putative environmental toxins might also be considered. In addition, in those families afflicted with manic–depressive disorder across generations, those in later generations tend to have earlier onset; this phenomenon, called anticipation, may be due to changes in genetic loading across generations, instability of genetic material, or environmental factors either within the family or in the wider environment (Lange and McInnis, 2002, O’Donovan et al. 2003; see also Section “Postconceptual Congenital Factors”). Regardless of the cause, the increasing incidence and earlier onset of manic–depressive disorder indicate that this illness is not likely to decrease in importance as a clinical and public health issue.

**Comorbidity**

Psychiatric and medical comorbidity in manic–depressive disorder has been increasingly recognized since the last edition of this textbook. At that time, only substance use disorders warranted specific summary. We now recognize that anxiety disorders are at least equally common among individuals with manic–depressive disorders, and that several other psychiatric disorders and many medical disorders are also common. In fact psychiatric comorbidity is the rule rather than the exception, with 57.3% (Bauer et al. 2005a) to 74.3% (Jacobi et al. 2004) having at least one active comorbidity, and 14.9% (Jacobi et al. 2004) to 29.8% (Bauer et al. 2005a) have two or more. Medical comorbidity rates are even higher, and both worsen outcome and constrain treatment (see Section “Medical Comorbidity”).

**Substance Use Disorders**

Some prevalence studies are conducted with community-based sampling, i.e., interviewing subjects regardless of whether or not they are receiving any kind of health care. Other studies are conducted on clinical samples whose members are, by definition, receiving healthcare services of some type. Whereas in the general population rates of alcohol abuse combined with alcohol dependence range from 3 to 13%, they are greater than 30% in persons with manic–depressive I disorder (Regier et al. 1990). Further, lifetime rates for drug dependence in individuals with manic–depressive I disorder are greater than 25%, and rates for any substance abuse or dependence are above 60%;...
comparable rates for alcohol, drug, or any substance abuse or dependence in major depressive disorder in ECA data are, respectively, 12%, 11%, and 27% (Regier et al. 1990).

Substance use disorder comorbidity rates in clinical samples have recently been reviewed (Bauer et al. 2005a). Rates are high, but vary widely depending on whether the sample is inpatient or outpatient, and whether lifetime or current rates are ascertained (Table 67–6). Importantly, there is some evidence from large samples of individuals with manic–depressive disorder that rates of these disorders may vary depending on whether the samples reflect populations receiving health care in the public sector versus private institutions (Bauer et al. 2006a). For example, individuals recruited for a clinical trial of a care management intervention within the VA system (n = 306) had SCID-defined lifetime substance use disorder rate of 72% and current rate of 34%, similar to the screen-positive rate of substance use disorders of 55% in a clinical trial in a Texas community mental health setting (n = 409). In contrast, clinical trial or cohort samples of 261–1,000 subjects across three private sector studies revealed rates of 4–12% current substance use disorders. Thus these public sector rates more closely resemble community rates, raising the question of selection or barriers to entry into private sector health care for such dually diagnosed individuals.

**Anxiety Disorders**

Community-based studies from several countries have investigated anxiety comorbidity in manic–depressive disorder. Lifetime anxiety disorder diagnosis in a Canadian sample of individuals with manic–depressive disorder was 51.8% (Schaffer et al. 2006), while lifetime rates for individual anxiety disorders in a Hungarian sample ranged from 12.5 to 22.1% (Rihmer et al. 2001). Among US individuals over 65 years of age, lifetime rates of panic and generalized anxiety disorders were, respectively, 19.0% and 20.5%, while current rates were, respectively, 11.9% and 9.5% (Goldstein et al. 2006). Anxiety disorders have been found in 33.3% of a community sample of adolescents with manic–depressive disorder as well (Lewinsohn et al. 1995).

Current anxiety rates in clinical samples (Table 67–7) match or exceed those for substance use disorders. As with substance use disorders, rates tend to be higher in inpatient samples than outpatients. Lifetime rates of all individual anxiety disorders appear to be substantial, while current rates are particularly notable in panic disorder (8–17%) and posttraumatic stress disorder (4–40%) (Bauer et al. 2005a, McIntyre et al. 2006c). Notably, there is less difference between current and lifetime rates than for substance use disorders suggesting that, from a population perspective, these disorders represent a chronic problem. Interestingly, comparison of anxiety disorder rates across large clinical cohorts recruited in the public versus private sector does not indicate the same disparity as for substance use disorders (Bauer et al. 2006a), suggesting that this comorbidity does not represent a barrier to private sector treatment.

**Other Psychiatric Comorbidity**

While attention-deficit hyperactivity disorder (ADHD) represents an alternative diagnostic possibility for manic–depressive disorder, there appears to be evidence that these distinct disorders also co-occur. In a predominantly adult clinical sample ADHD lifetime and current rates were found to be, respectively, 9% and 6% in youth (see Section “Treatment of Manic–Depressive Disorder Across the Life Cycle”) and adults (Simon et al. 2004a).

In community samples of persons with manic–depressive disorder, lifetime rates of eating disorders range from 0 to 9% (McElroy et al. 2006a). In clinical samples, the lifetime rates of any eating disorder range from 8 to 27% (Simon et al. 2004a, McElroy et al. 2006a).

The relationship of manic–depressive disorder to borderline personality disorder has long been a subject of debate and scientific interest. Some have maintained that there is little to no relationship between the two (reviewed in Gunderson et al. 2006) while others have suggested that the two clinical syndromes are part of a single continuum (e.g., Akiskal 2004). Recent genetic studies suggest that there may be a link between manic–depressive disorder and personality or temperament (not necessarily borderline), yet much remains conjectural (e.g., Savitz and Ramesar 2006, Serretti et al. 2006). Perhaps the highest quality data to address the relationship of manic–depressive and borderline personality disorders come from the US National Institute of Mental Health (NIMH)-funded Collaborative Longitudinal Personality Disorders Study (Gunderson et al. 2000), in which subjects with a wide variety of personality disorders have been followed prospectively with standardized assessment tools. Four-year follow-up from this cohort supports a position between the above two poles. Specifically, compared to those with other personality disorders, individuals with borderline personality disorder have significantly higher rates of manic depression (19.4% vs. 7.9%), including both type I (11.7% vs. 5.5%) and type II (7.7% vs. 2.3%) disorder, and tend to have higher prospectively documented incidence rates (p = 0.07); however, manic-depression comorbidity rates are lower in borderline personality disorder than those
for major depression, PTSD, or substance use disorders (Gunderson et al. 2006).

Medical Comorbidity
Evidence is accumulating that comorbid medical conditions are highly prevalent, worsen outcome, limit treatment options, and are induced or exacerbated by certain treatments. A variety of studies have documented high, or significantly increased, rates of medical comorbidity among individuals with manic–depressive disorder (Table 67–8; also recently reviewed in Newcomer, 2006). Over 80% have at least one active medical problem while 19–23% have two such conditions and 35–50% have three or more (Kilbourne et al. 2004, Fenn et al. 2005). In addition, several relatively low prevalence illnesses may be significantly increased in individuals with manic–depressive disorder compared to the population without this disorder, including chronic obstructive pulmonary disease, hepatitis C, and HIV (Kilbourne et al. 2004), migraine headaches (McIntyre et al. 2006b), and accidents and musculoskeletal trauma (Kilbourne et al. 2004, Beyer et al. 2005). Over half of those with manic–depressive disorder may be overweight, and 27% may be obese (Wang et al. 2006).

| Table 67–8 Prevalence Rates (%) of Selected Common Medical Disorders in Clinical Samples of Individuals with Manic–Depressive Disorder |
|--------------------------------------------------|------------------|------------------|
| Tobacco use                                      | Inpatient: 54–68% | Outpatient: 20–49% |
| Obesity                                          | 3–50%            |
| Cardiovascular disease and hypertension           | 13–39%           | 18–51%           |
| Hyperlipidemia                                    | 23–24%           | 2–13%            |
| Diabetes                                         | 4–18%            | 30–31%           |

Increased rates of medical comorbidity have been associated with increased depression severity and worse treatment outcome (Thompson et al. 2006, McIntyre et al. 2006a), though not all studies have found this relationship (e.g., Beyer et al. 2005). Medical comorbidity has also been associated with worse function (McIntyre et al. 2006a) and physical quality of life (Fenn et al. 2005). One study has demonstrated reduced time to episode recurrence with obese individuals with manic–depressive disorder (Fagiolini et al. 2003), while another has found an increased rate of “natural death,” which was associated with several medical findings including elevated liver transaminase levels and white blood cell counts (Tsai et al. 2005).

For decades clinicians have recognized that certain medical comorbidities limit the use of various psychotropic medications, for example, renal disease (lithium), liver disease (valproate, carbamazepine), cardiac arrhythmias (tricyclic antidepressants). More recently, clinicians have come to recognize that certain antipsychotic medications, particularly several of the second generation antipsychotics, are associated with weight gain, type II diabetes, and consequent increased cardiovascular risk (e.g., Correll et al. 2006, Guo et al. 2006, Ofsson et al. 2006). Intriguingly, not all the risk of diabetes is attributable to psychotropic use, and manic–depressive disorder itself may be a significant risk factor (Regenold et al. 2002).

Course

Defining Outcome: Clinical, Functional, Quality of Life, and Economic Outcomes
Several developments in society at large, in biomedical treatment in general, and in mental health research in particular, have led to an expansion of the purview for mental health research beyond simple symptom reduction to include understanding the impact of illness and its care on a patient’s overall quality of life and how to make the best use of available resources (Stewart et al. 1989, National Institute of Mental Health 1992, Leaf 1993). With this orientation, we can therefore conceptualize outcome in manic–depressive disorder according to three separate but interrelated domains: clinical outcome, functional outcome and quality of life, and illness costs. Clinical outcome consists of parameters that measure the illness itself, such as symptom severity, episode number, and duration. Functional outcome consists of social and occupational status and subjective quality of life. Illness costs consist of both direct (treatment) costs and indirect illness costs, which include lost productivity, necessary nontreatment social supports, and nontreatment interventions such as jail and the legal system. Each domain is reviewed below.

Clinical Outcome
Manic–depressive disorder has its onset in most persons in adolescence and young adulthood, between the ages of 15 and 30. However, prepubertal mania and first-onset disease in the 9th decade of life are not unheard of. Once developed, multiple episodes are the rule. There is no typical pattern to episode recurrence, with some patients having isolated manic, hypomanic, or depressive episodes, others switching from one pole to the other in linked episodes, and still others switching continually from one pole to the other in quasicyclical fashion (Angst 1981). However, even among rapid-cycling patients, episodes are rarely periodic. Rather, the pattern is more accurately described by chaotic dynamics (Gottschalk et al. 1995).

Episode length typically ranges from 4 to 13 months, with depressive episodes typically longer than manic or hypomanic episodes (Goodwin and Jamison 1990, p 40). Women appear to have more depressive than manic episodes, whereas men have a more even distribution (Angst 1981). Also women predominate among rapid-cycling patients, representing 70–90% in most studies (Bauer and Whybrow 1993, Bauer et al. 1994b).

Manic–depressive disorder had been separated from dementia praecox (schizophrenia) by Kraepelin (1989) on the basis of relatively favorable outcome in terms of remitting versus chronic course of psychosis. However, this relatively optimistic view contrasts with the overall guarded prognosis described by most longitudinal studies in the last 3 decades, which have been less controlled but more inclusive than formal clinical trials. In the early studies, the majority had equivocal to poor outcome (Levinstein et al. 1966, Winokur et al. 1969) and almost half were chronically ill (Bratfos and Haug 1968). Although these studies include data from the prelithium era, studies since the development of modern psychopharmacology are not reassuring. Approximately 20–40% of patients with manic–depressive disorder do not respond well to lithium (Prien and Gelenberg 1989), and
that proportion may increase to as much as 80% for certain subgroups such as those with rapid-cycling (Dunner and Fieve 1974, Maj et al. 1989) or mixed episodes (Keller et al. 1986). Up to one-third of individuals remain chronically ill (Keller et al. 1986a), and one-quarter to one-third of hospitalized individuals go on to poor outcome or chronicity (Tohen et al. 1990, Harrow et al. 1990); further, 60% of an ambulatory sample of manic-depressive patients had fair to poor outcome based on a global outcome score after 1-year follow-up (O’Connell et al. 1991).

Since the last edition of this textbook, analyses of two large studies have provided a detailed look at prospective outcome. The NIMH Collaborative Study on the Psychobiology of Depression, begun in the 1970s, has now analyzed data from subjects for up to 20 years (Judd et al. 2002, 2003a–2003c). These data confirm the overall guarded prognosis for manic-depressive disorder. Individuals with type I disorder spent 46.6% of weeks with clinically significant symptoms, while those with type II disorder spent 55.8% of weeks symptomatic. Depressive weeks outnumbered manic weeks by 3:1 in both type I and type II though other analyses indicated more depressed weeks in type II. Notably, substantial amounts of time were spent with clinically significant symptoms that did not meet criteria for a full affective episode (Judd et al. 2003c), a finding in agreement with a large population-based cross-sectional study (Bauer et al. 2003a). Lack of a firm, categorical cut-off between DSM-defined episodes and subsyndromal symptoms is also supported by lack of difference between individuals with type II disorder who experienced 2–6 day hypomanic episodes versus those with longer hypomanias (Judd et al. 2003a). These data are consistent with earlier studies (e.g., Nilsson and Axelsson 1989, Harrow et al. 1990). These analyses extend our knowledge of type II disorder, but remain equivocal regarding whether type I and type II are distinct disorders. The NIMH Collaborative Study found no differences in baseline demographic or clinical characteristics or substance comorbidity between type I and type II though other analyses indicated more depressed weeks in type II. Notably, substantial amounts of time were spent with clinically significant symptoms that did not meet criteria for a full affective episode (Judd et al. 2003c), a finding in agreement with a large population-based cross-sectional study (Bauer et al. 2003a). Lack of a firm, categorical cut-off between DSM-defined episodes and subsyndromal symptoms is also supported by lack of difference between individuals with type II disorder who experienced 2–6 day hypomanic episodes versus those with longer hypomanias (Judd et al. 2003a). These data are consistent with earlier studies (e.g., Nilsson and Axelsson 1989, Harrow et al. 1990). These analyses extend our knowledge of type II disorder, but remain equivocal regarding whether type I and type II are distinct disorders. The NIMH Collaborative Study found no differences in baseline demographic or clinical characteristics or substance comorbidity between the types, though did find that type II was characterized by higher rates of anxiety comorbidity. Not surprisingly, intake episode severity was greater for type I (perhaps accounted for by manic compared to hypomanic severity), but those with type II received less intense pharmacotherapy (Judd et al. 2003c). The two types were found to have similar levels of social dysfunction (Correll et al. 1989b, Judd et al. 2005). However, type II individuals appear to spend more time depressed than type I individuals (Judd et al. 2003b), while type I individuals appear to spend more time (hypo)manic than type II individuals (Judd et al. 2003b).

The second large study is the Systematic Treatment Enhancement Program for Bipolar Disorder (Sachs et al. 2003). This NIMH-funded program consisted of a long-term cohort follow-up study with several embedded randomized controlled trials. Cohort analyses indicated a predominance of depressive episodes in this mixed type I and II sample, with 29–41% of days depressed versus 19–20% of days “elevated” over 2 years of follow-up (Perlis et al. 2005). Notably, only 58.4% recovered from their index episode at study entry. In those who did recover, depressive relapses outnumbered (hypo)manic relapses by more than 2:1; the time for 25% of the sample to relapse was 21.4 weeks for depression, and 85.0 weeks for (hypo)mania (Perlis et al. 2006b). There are few predictors of recurrence that would not be expected a priori (Perlis et al. 2006b), such as more prior episodes, more chronicity of symptoms, and more residual symptoms each predict shorter time to relapse; although women apparently have shorter time to relapse than men, gender is not a significant predictor when these other factors are accounted for. Notably, current anxiety disorders predict shorter time to depressive relapse while current substance disorders predict shorter time to manic relapse.

Functional Outcome and Health-Related Quality of Life

Substantial levels of functional impairment are characteristic of manic-depressive disorder, even when major clinical indices have improved. The book-length study of manic-depressive patients in the prelithium era by Winokur et al. (1969) documented their sample’s functional impairment in detail. For instance, 79% of those employed before their index episode lost their jobs during that episode. Among those with incomplete remission during follow-up, 73% had long-term decrements in occupational status. Even more striking, 25% of those with complete remission or only infrequent episodes developed similar occupational decrements. In another early study, 60% had less than satisfactory social recovery (Hastings 1958). In a study of persons with manic-depressive disorder treated at the NIMH, only 41% had returned to their jobs at 3 years of follow-up, and 15% were totally unemployed. Forty-five percent had normal family and social function, 21% evidenced “complete social withdrawal,” and 11% “complete family disruption” (Carlson et al. 1974). On global outcome assessment, 57% were judged recovered, 10% had intermittent episodes, and 28% were functionally impaired with moderate to severe affective symptoms. In contrast, Dion et al. (1988) found that although 80% of their sample of manic-depressive patients became symptom free by 6 months after an index major affective episode, only 43% were employed and only 21% were employed at preepisode levels. Harrow et al. (1990) found at 1.7 years of prospective follow-up after an index manic episode that only 23% of patients were continuously unemployed, with 36% underemployed in comparison to preepisode levels. Occupational function was significantly worse than in a comparison group of depressive patients without history of mania. In addition, 36% showed at least moderate impairment in social function. These deficits were unrelated to the presence of symptoms, with the exception of psychosis, which was associated with profound impairment. Tohen et al. (1990) found 28% of subjects unemployed after index hospitalization for mania. Bauwens et al. (1991) found that levels of functional disability correlated both with number of prior episodes and with residual interepisode psychopathology.

Far and away the strongest predictor of functional deficits is ongoing depressive symptoms, even in mild degree (reviewed in Bauer et al. 2001b, Judd et al. 2005). The direction of causability is not clear, however. It is plausible that depressive symptoms render individuals less able to function in work and personal roles. It is equally plausible that unemployment, divorce, social isolation, and the like can cause or exacerbate depressive symptoms. In fact, both are likely. In any event, careful attention to functional deficits, depressive symptoms, and their
interplay is important to optimizing care and hopefully outcome.

Health-related quality of life—by definition a self-reported, subjective summary judgment regarding how one is functioning in the world—has been the subject of recent study in manic–depressive disorder. Mental quality of life in manic–depressive disorder is consistently well below population norms (e.g., Voight et al. 2001, Zhang et al. 2006). As with social role function, the strongest predictor of poor quality of life is depressive symptoms (Voight et al. 2001), even after control for numerous potential confounds (Zhang et al. 2006).

Manic–depressive disorder is characterized by high rates of suicidality. Suicide attempt rates may be as high as 2%/year (Baldessarini et al. 2001). Rates of completed suicide may be as high as 7–19% (Goodwin and Jamison 1990, Angst 2002), and may be 15-fold higher than in the general population (Harris and Barraclough 1997).

Economic Outcome: Direct and Indirect Illness Costs
The Global Burden of Disease Study (GBDS) has ranked manic–depressive disorder sixth in disability worldwide (Murray and Lopez 1996, Lopez and Murray 1998). It is the most expensive mental disorder for US private behavioral health plans (Peele et al. 2003) and employers (Goetz et al. 2003). Individuals with manic–depressive disorder receive care throughout the healthcare system (Simon and Unützer 1999, Das Gupta and Guest 2002), and up to 70% of direct treatment costs are generated outside the mental health sector (Begley et al. 2001, Bryant-Comstock et al. 2002). Lifetime total costs per patient exceed US $250,000 (Begley et al. 2001). If one can extrapolate to manic–depressive patients from the data for aggregate mental illness costs (McGuire 1991), 55% of treatment costs derive from public sector services and 45% from the private sector.

The high suicide rates in manic–depressive disorder place a substantial proportion at high risk of loss of life through this one cause alone, while excess mortality (see Section “Medical Comorbidity”) adds to the economic cost of early loss of life. Without adequate treatment, a person with manic–depressive disorder from age 25 years can expect to lose 14 years of effective major activity (e.g., work, school, family role function) and 9 years of life (US Department of Health, Education, and Welfare 1979). The indirect costs of bipolar disorder are high as well, with substantial costs incurred by both work absence and reduced efficiency at work. For instance, a Dutch study indicates that yearly indirect costs due to bipolar disorder may total as much as $1.37 billion dollars, over three-fold the total direct treatment costs for the disorder (Hakkaart-van Roijen et al. 2004), underlining the substantial functional impact bipolar disorder can have on society.

Differential Diagnosis
Differential diagnosis of manic–depressive disorder can be simplified by keeping in mind that the disorder, in classic form, consists of discrete episodes of (hypo)mania, depression, or their combination. Focus on discrete episodes is particularly important since a wide variety of behaviors can raise the suspicion of (hypo)mania, and since an unintended consequence of the appropriate attention to this disorder in the lay press has led in some quarters to its becoming a diagnosis du jour, too easily applied to chronic, aberrant behaviors that are not due to this illness.

As with all psychiatric disorders, underlying medical causes must be ruled out, as must untoward effects of medications. Illnesses and medications that have been associated with (hypo)manic episodes are found, respectively, in Tables 67–2 through 67–5. Recall that medication history should include not only those prescribed by physicians but also those that are self-prescribed (over-the-counter and herbal/supplements) and drugs of abuse (both illegal and legal). Similarly, medical and medication causes of depressive episodes can found in Chapter 66.

Individuals with recurrent major depressive disorder will often not recognize or report prior hypomanic or even manic episodes, so these must be queried for specifically. Several other Axis I disorders present with psychomotor hyperactivity or what appears to be decreased need for sleep (not just insomnia), such as, ADHD and PTSD; however, the former is typically chronic and the latter associated with prior trauma and trauma-related themes in the hyperactivity or sleeplessness (e.g., hypervigilance or fear of sleep).

Similarly, borderline personality disorder frequently involves mood lability, instability of interpersonal relationships, periodic feelings of emptiness or identity disturbance, and episodes of self-harm—all of which can be found in manic–depressive disorder, particularly the rapid-cycling variant. While psychodynamic formulation can frequently differentiate the former from the latter, even on purely descriptive grounds temporal course and relationship features clarify the diagnosis. Specifically, in manic–depressive disorder discrete several-day episodes are the rule, and they are not necessarily linked to discrete stressors such as interpersonal rejection; moreover, in this disorder history usually reveals that when the mood is stable the individual’s patterns of interpersonal relationship often stabilize—though there is no question, as summarized above, that individuals with this disorder are often impoverished interpersonally due to their illness.

It should also be kept in mind that the differential diagnosis in individuals with possible manic–depressive disorder is often an issue of and rather than or. That is, since the majority of such individuals have some psychiatric comorbidity, anxiety, substance, and attention-deficit, and medical disorders are often present as concurrent comorbidities rather than alternative diagnoses (see Section “Comorbidity”). Comprehensive care depends on identifying and treating each of these.

Finally, it should also be noted that manic–depressive disorders likely represent part of a spectrum both with other mood disorders and perhaps other disorders (e.g., Perugi and Akiskal 2002) including schizophrenia (e.g., Craddock and Owen 2005, MacQueen et al. 2005, Potash 2006). Thus while classic textbook cases are readily identified, it is expected that a variety of individuals will inhabit the boundaries of this disorder, which, as most psychiatric diagnoses, is likely best considered a “fuzzy set.”

Age, Gender, and Cultural Issues in Diagnosis and Assessment
Manic–depressive disorder is a worldwide problem, with manic–depressive disorder among the top 10 of all diseases...
in terms of global burden worldwide, and sixth in terms of self-reported disability (Andrews et al. 1998). There are no major differences in the manifestations of manic–depressive disorder across gender, the adult lifespan, race/ethnicity, or culture. However, women appear to be at higher risk for rapid cycling (Bauer and Whybrow 1993, Bauer et al. 1994b), dysphoria during mania (McElroy et al. 1992, Bauer et al. 1994c), and comorbid disorders (Strakowski et al. 1992 and 1994). Note also that affective psychoses may be relatively underdiagnosed, and schizophrenia overdiagnosed, in African-Americans compared to Caucasians (Strakowski et al. 1993).

Among children and adolescents, the diagnosis of manic–depressive disorder is often complicated by less consistent mood and behavior baseline than occur in adults (Carlson and Kashani 1988). Little evidence is available regarding course and outcome in children. Available data indicate that, as with adults, mixed or cycling episodes predict more recurrences; unlike in adults, manic and mixed presentations may be associated with relatively shorter episodes compared with depressive presentations (Strober et al. 1995). Notably, attentional and executive cognitive deficits may remain in euthymic young adults who have experienced even one or two mood episodes as children (Kolur et al. 2006).

### Etiology and Pathophysiology

Review references outlining the various hypotheses of manic–depressive disorder are provided in Table 67–9. No single paradigm can explain the occurrence, and variability in course and severity of manic–depressive disorder. Rather, an integrative approach to understanding the causes of manic–depressive disorder is needed, which recognizes the contributions of a variety of biological, psychological, and social factors, as articulated in George Engel’s biopsychosocial model (Engel 1977).

### Genetic and Congenital Hypotheses

#### Family, Twin, and Adoption Studies

Available evidence indicates that familial factors are important determinants of who will develop manic–depressive disorder. Numerous studies have shown that relatives of manic–depressive probands (identified cases) have higher rates of manic–depressive disorder than controls or unipolar probands (Table 67–10). Overall, rates of manic–depressive disorder in first-degree relatives (parents, siblings, children) of probands with manic–depressive disorder are elevated 5–10 times over rates found in the general population. In the latter group, the rates are 0.5–1.5%, while in the former group rates are 4–15% (Table 67–10). Polarity of first episode may also be familial (Kassem et al. 2006). Interestingly, rates of unipolar depression in first-degree relatives of individuals with manic–depressive disorder are elevated about twofold over those in the general population, or about 20–40%. Important for genetic counseling, this in turn means that the probability that a manic–depressive proband will have a unipolar child is greater than the probability that they will have a manic–depressive child; note that it is most likely that they will have neither.

Most genetic research has been done on type I disorder. However, type II also appears to have a familial

component. Type II probands have more type I disorder and more type II disorder than unipolar depressives and less type I disorder than type I probands (Endicott et al. 1985, Simpson et al. 1993).

Familial occurrence does not differentiate between inborn and environmental factors. Familial aggregation could be due to sharing genetic material, nongenetic congenital factors (e.g., similar inherited or acquired intrauterine factors, or exposure to similar perinatal risk factors), or psychologic or psychological environmental factors. Data from other types of studies indicate that at least part of this risk is due to biological, and likely genetic factors. Twin studies indicate that monozygotic twins (derived from a single egg and sperm and therefore having an identical genome) have higher concordance rates for manic–depressive disorder than do dizygotic twins (derived from fertilization of two eggs); 60–80% for monozygotic twins versus 20–30% for dizygotic twins (Price 1968, Bertelsen 1979). Further, one adoption study showed that rates of manic–depressive disorder in persons adopted away from their biological families are closer to those in the biological families than the adoptive families (Price 1968, Mendlewicz and Rainer 1977). Finally, linkage studies (see the next section) have suggested that in certain families manic–depressive disorder may be linked to specific genes. On the other hand, studies of monozygotic twins also indicate that only 40–70% are concordant for manic–depressive disorder. Thus, although there is clearly a genetic component to this illness, genetics is not destiny.

Molecular Genetic Studies
Among the fastest growing areas of research since the last edition of this textbook has been psychiatric genetics. Most profoundly, there is a growing recognition that the factors that are transmitted genetically (endophenotypes) may not correspond well to preestablished DSM-defined disorders. In some cases, disorders previously considered quite distinct descriptively may be shown to share genetic diatheses (e.g., manic depression and schizophrenia; Craddock and Owen 2005, Potash 2006). A related approach to investigating genetic contributions to manic–depressive disorder is to look for differences in genes that code for components of systems thought to be involved in the pathophysiology of the disorder. Chief among such candidate genes have been those responsible for dopamine and serotonin receptors or metabolic enzymes (Potash and DePaulo 2000), the norepinephrine-metabolizing enzyme catechol-O-methyl transferase (COMT; Lachman et al. 1996, Kirov et al. 1998, Mynett-Johnson et al. 1998, Papolos et al. 1998), brain-derived neurotropic factor, which may be involved in stress response or antidepressant mechanisms (Neves-Perreira et al. 2002, Sklar et al. 2002), and the serotonin transporter (e.g., Mansour et al. 2005, Masoliver et al. 2006). Meanwhile, search is underway for the genetic basis of clinical characteristics that may represent relevant endophenotypes for manic–depressive disorder, including circadian rhythm and sleep parameters, electrophysiologic evoked potentials, response to stimulants, monocyte characteristics, and a series of neuroimaging and cognitive features (MacQueen et al. 2005).

In addition, it is possible that the expression of a psychiatric illness that is coded genetically may not be due simply to the presence or absence of specific genes, but rather to modifying pieces of DNA in close proximity to important genes. Specifically, small sections of DNA, three base-pairs in length (called trinucleotide repeats), appear to be overrepresented in genetic disorders with prominent psychiatric symptoms such as fragile X syndrome and Huntington’s disease. The disproportionate number of trinucleotide repeats are hypothesized to be responsible for over- or underexpression of candidate genes, ultimately leading to neuropsychiatric symptoms (Petronis and Kennedy 1995). Recent evidence indicates that this mechanism may also be relevant to manic–depressive disorder (e.g., Lindblad et al. 1998, Lange and McInnis 2002, Swift-Scanlon et al. 2005), including the phenomenon of anticipation (see Section “Epidemiology”), although studies are far from conclusive for any genetic locus (Jones et al. 2002, O’Donovan et al. 2003).

Postconceptual Congenital Factors
There has been little exploration of nongenetic congenital factors that may be responsible for manic–depressive disorder, although it is reasonable to suppose that intrauterine or perinatal factors that produce brain injury may lead to manic–depressive mood syndromes, just as head trauma during life may lead to mood disorders as well as cognitive impairment. Intriguingly, trinucleotide repeats may actually change over the postconceptual period (i.e., during development) leading to neuropsychiatric symptoms (Petronis and Kennedy 1995). Recent evidence indicates that this mechanism may also be relevant to manic–depressive disorder (e.g., Lindblad et al. 1998, Lange and McInnis 2002, Swift-Scanlon et al. 2005), including the phenomenon of anticipation (see Section “Epidemiology”), although studies are far from conclusive for any genetic locus (Jones et al. 2002, O’Donovan et al. 2003).

Intriguingly, trinucleotide repeats may actually change over the postconceptual period (i.e., during development) leading to neuropsychiatric symptoms (Petronis and Kennedy 1995). Recent evidence indicates that this mechanism may also be relevant to manic–depressive disorder (e.g., Lindblad et al. 1998, Lange and McInnis 2002, Swift-Scanlon et al. 2005), including the phenomenon of anticipation (see Section “Epidemiology”), although studies are far from conclusive for any genetic locus (Jones et al. 2002, O’Donovan et al. 2003).
Neurobiologic Factors

A wide range of neurochemical, neuroendocrine, neuroanatomic, and neurophysiologic hypotheses have been put forward regarding the biological basis of manic–depressive disorder. The major hypotheses have been recounted in great detail in the excellent and still reasonably current review by Goodwin and Jamison (1990, pp 422–423) but has not been extensively of catechol systems leading to manic and depressive episodes in Europe (e.g., Coppen et al. 1972), and a “permissive hypothesis” whereby serotonin alterations permit instability of catechol systems leading to manic and depressive episodes has been articulated in broad strokes by Goodwin and Jamison (1990, pp 422–423) but has not been extensively developed. Implication of the serotonin transporter has enhanced interest further, although its relevance in manic–depressive disorder is not yet clear (e.g., Mansour et al. 2005, Masoliver et al. 2006).

Janovsky et al. (1973) proposed that acetylcholine deficits were associated with mania. As with the serotonin hypothesis, this theory posits that the cholinergic system also interacts with the catecholaminergic system to produce affective instability.

Recent evidence also suggests that gamma-aminobutyric acid (GABA) may also be involved in the pathophysiology of manic–depressive disorder (Post et al. 1992, Petty et al. 1993, 1996, Benes and Berretta 2001). Glutaminergic neurotransmission has also been a focus of more recent interest, based on in vitro data and in vivo neuroimaging studies; interestingly, this line of research requires broadening the focus of research from the neuron to include the glial cell as well (Kugaya and Sanacora 2005).

Second-Messenger System Hypotheses

Since the first edition of this textbook, substantial research has focused on the role of postreceptor intracellular mechanisms known as second-messengers (and sometimes third- and fourth-messengers). This research is well summarized in several recent reviews (Stahl 2000, Sassi and Soares 2002, Bezchlibnyk and Young 2002, Coyle and Duman 2003). When neurotransmitters bind to postsynaptic neuronal receptors, a series of intracellular events are initiated that are mediated by chemical systems linked to those receptors. G-proteins link the receptors to second-messenger systems, which in turn are linked to protein kinases that control the synthesis and operation of cellular components (Sassi and Soares 2002).

The cyclic AMP and phosphatidyl inositol systems are the most extensively studied of these second-messenger systems. The phosphatidyl inositol system may mediate the clinical effects of lithium in manic–depressive disorder; particularly since this second-messenger system is linked to subtypes of adrenergic, serotonergic, dopaminergic, and cholinergic neurotransmitter systems. Specifically, lithium at therapeutically relevant concentrations has been demonstrated to inhibit phosphatidyl inositol turnover in cultured cell lines and animal studies (El-Mallakh and Li 1993, Lenox and Watson 1994). G-protein levels may be altered in individuals with manic–depressive disorder, and lithium modulates the efforts of several G-proteins (Bezchlibnyk and Young 2002). Lithium and valproate reduce phosphokinase activity (Manji and Lenox 2000). A variety of abnormalities of the cyclic AMP system have also been demonstrated in human and animal in vitro studies (Bezchlibnyk and Young 2002). These agents, and perhaps carbamazepine, ECT, and lamotrigine, also affect second-messenger systems involved in cellular growth and degeneration (Coyle and Duman 2003; see also Section “Cell Degeneration and Neuroprotective Effects of Medications”). Further, several preclinical and clinical studies suggest that manic depression may be associated with abnormalities in intracellular calcium metabolism, which is involved in signal transduction, synaptic plasticity, and cell death (Bezchlibnyk and Young 2002).

In clinical studies, persons with manic–depressive disorder have demonstrated alterations in platelet phosphatidyl inositol levels (Brown et al. 1993) and responsiveness of neutrophil phosphoinositol accumulation
Neuroendocrine Hypotheses

Neuroendocrine hypotheses have sought to elucidate mechanisms in the production and maintenance of symptoms rather than identify a specific etiologic agent in manic–depressive or other mood disorders. These hypotheses were developed from the literature on stress response in otherwise normal subjects (Mason 1975). Typical neuroendocrine studies investigate peripheral or cerebrospinal fluid abnormalities of a particular system in persons with mood disorders and in controls and propose that either the neuroendocrine system itself or the neurotransmitter system that controls the hormone is in some way linked to the pathophysiology of the mood disorder of interest. Perhaps the most complete battery of neuroendocrine assessments in manic–depressive disorder was conducted by Amsterdam et al. (1983). Taken together, the literature does not identify specific endocrine findings as characteristic of manic–depressive disorder.

However, the thyroid axis may be of particular relevance since supplementation with high doses of the thyroid hormone thyroxine (T4) may induce remission in individuals with rapid cycling who are refractory to standard pharmacotherapy, an effect that is independent of thyroid status or history (Bauer and Whybrow 1990). The mechanism for these effects has been the subject of much speculation. Various models posit that the brain is functionally hypothyroid either due to changes in hormone synthesis, transport, or metabolism, or due to increased demand; alternatively, other models propose that the brain has an excess of a thyroid-related substance, which administration of exogenous thyroid hormone diminishes (Bauer and Whybrow 1990, 2001, Joffe et al. 1993).

Neuroanatomic Hypotheses

Two main types of studies have provided information on the possible neuroanatomic bases of manic–depressive disorder. First, persons with brain injuries who develop a phenomenologically manic–depressive picture have been analyzed, often neuropathologically, to determine sites of injury that may have produced the manic–depressive clinical picture. For example, lesions of the right side of the brain, particularly frontotemporal lesions, may be associated with manic-like syndromes (Starkstein et al. 1988).

Second, as recently reviewed by Strakowski et al. (2005), persons with manic–depressive disorder who do not have a known organic basis for their illness are studied either with structural (computerized tomography, magnetic resonance imaging [MRI]) or functional imaging (single photon [SPECT] or positron [PET] emission tomography, or functional MRI or spectroscopy [MRS]) to identify regions of abnormality. Although this area is rapidly growing, it is useful to keep in mind that few studies have compared individuals with manic–depressive disorder to those with other serious mental illnesses, so the specificity of findings is not clear. Fewer, further studies have assessed first-episode, untreated subjects, so the degree to which anatomic abnormalities reflect pathogenic factors, as opposed to end organ damage or effects of chronic medication usage, is unclear. Several structural imaging studies have demonstrated volume reductions in the subgenual prefrontal cortex (e.g., Drevets et al. 1997, Hirayasu et al. 1999, Brambilla et al. 2002), which may occur early in illness (Hirayasu et al. 1999). Increased volume of the corpus striatum has also been found in several studies, and may also be an early illness finding (e.g., Strakowski et al. 2002, Delbello et al. 2004). Several studies have also demonstrated enlargement of the amygdala (e.g., Strakowski et al. 1999, Altshuler et al. 2000, Brambilla et al. 2003).

There has been substantial interest in quantitating and localizing so-called “T2 hyperintensities” found in MRI studies, thought to represent increased water content of microregions of the brain. These findings are nonspecific, and no consistency regarding prevalence or distribution in manic–depressive disorder has yet been demonstrated (Altshuler et al. 1995b, Yildiz et al. 2001). A wide ranging and complex magnetic resonance spectroscopy literature suggests that individuals with manic–depressive disorder may have evidence for reduced cellular integrity in several prefrontal or striatal areas, though the degree to which these findings are specific to the pathogenesis of disorder, or are due to treatment or nonspecific damage, is not clear; similar concerns attend to findings of altered whole-brain energy metabolism (Strakowski et al. 2005).

A variety of functional imaging studies using PET or SPECT have demonstrated reduced blood flow or metabolism during bipolar depressive episodes (Strakowski et al. 2005), with some evidence that such parameters are increased during mania (Drevets et al. 1997, Blumberg et al. 2000), though the consisting of such findings will likely depend on the ability of imaging tools to identify specific prefrontal subregions. The strategy of combining functional imaging studies, such as FMRI, with cognitive activation tasks that depend on known neural circuitry represents an intriguing method to increase anatomical specificity of such findings (Strakowski et al. 2005).

Finally, it should be noted that a variety of PET studies have investigated serotonin receptor or transmitter binding and dopamine receptor binding in various brain regions (Strakowski et al. 2005). Though there is as yet little consistent evidence regarding abnormalities in manic–depressive disorder, development of higher resolution imaging techniques and multimodal strategies combing in vivo receptor binding with cognitive and/or pharmacologic challenges make this an area worth watching.

Cell Degeneration and Neuroprotective Effects of Medications

One of the most exciting areas of recent research focuses on the possibility that lithium, and perhaps antidepressants and certain anticonvulsants such as valproate, may actually exert a neuroprotective effect in manic–depressive disorder. Evidence indicates that these agents may protect nerve cells by stimulating production of protective proteins, regulating a variety of protein kinases, or by stimulating nerve
growth (Manji and Duman, 2001, Chen and Manji, 2006). Such factors may differentiate manic-depressive disorder from schizophrenia (Benes et al. 2006, Dean et al. 2006). Interestingly, there is some MRI evidence that lithium treatment may be associated with normalization of the reduced volume of total gray matter in manic depression (Manji and Lenox 2000, Moore et al. 2000).

Hypotheses Regarding Complex Physiologic Systems

Several complex systems, which for want of a better alternative are grouped together in this section as “physiologic” systems, have been postulated to play a pathogenic role in manic-depressive disorder. Classic theories of membrane and electrolyte imbalance (Goodwin and Jamison 1990, pp 467–481) have been extensively investigated in the past but appear, for the time being, to have passed out of favor. Similarly, kindling theory was once quite popular (e.g., Post et al. 1985, 1986a, 1986b), proposing an analogy between episodes in manic-depressive disorder and seizures in animal models of epilepsy, both of which were proposed to initially be stimulus driven but then to progress to autonomous occurrence. The theory provided an explanation for some effects of anticonvulsants in manic depression, but clinical data in support of the theory are scant (Bauer and Whybrow 1991).

A role for biological rhythms in the pathogenesis of manic-depressive disorder is suggested by two types of data. First, there are a large number of observational studies that have demonstrated seasonal peaks in the onset of affective episodes or hospitalizations for mood disorders. For manic-depressive disorder, the predominant seasons appear to be spring and fall (Goodwin and Jamison 1990, Kamoi et al. 1993), although other patterns may occur with some consistency across years (Faedda et al. 1993). In addition, in seasonal affective disorder, codified in DSM-IV-TR as “seasonal pattern,” a large proportion have manic-depressive disorder, and the clinical picture of winter depression is similar to the hypersonomolent, anergic, hyperphagic depression common in manic-depressive disorder (Bauer and Dunner 1993). Further, treatment with bright light has been shown to be efficacious in winter depression (Terman et al. 1989) and also appears to be an effective antidepressant in nonseasonal manic depression treated in the winter (Deltito et al. 1991) and perhaps in the summer (Bauer 1993); bright light also appears to be capable of inducing manic symptoms, as do other antidepressants (Bauer et al. 1994a).

The second type of data that suggest a biological rhythms mechanism is that persons with manic-depressive disorder often exhibit abnormalities of circadian (daily) rhythms. Many rhythmic parameters have been studied in persons with manic-depressive and other mood disorders, with various abnormalities found regarding the amplitude (height of the rhythm) and phase (timing of the rhythm) (Halaris 1987). Among the most promising findings is that light sensitivity to suppression of the hormone melatonin may be altered in persons with manic-depressive disorder (Lewy et al. 1980, 1985) and their relatives (Nurnberger et al. 1989). Further, one of the most striking findings in mania is the lack of need for sleep, and there is evidence that sleep deprivation may be both antidepressant and promanic (e.g., Wehr et al. 1982, Colombo et al. 1999).

Psychological Factors

Psychological Hypotheses

The psychological theories of mood disorders are wide ranging, including cognitive, behavioral, interpersonal, and psychoanalytic. Unfortunately, the bulk of theory regarding the psychological basis of mood disorders concerns depression, with little attention as yet to mania or manic-depressive disorder.

Cognitive theory regards depression as an affective response to negative beliefs (Beck et al. 1979, Rush and Hollon 1991). Attributions regarding events are based on unrealistically negative assumptions. When bad things happen, they happen because of one’s inadequacy, they will always happen, and similar bad things will happen in other situations. Relatively stable patterns of attribution develop relatively early in life, and misinterpretations of events and maladaptive responses are triggered by proximate events (Abramson et al. 1978, Seligman et al. 1979). Behavior theory views depression as a consequence of a low rate of response-contingent positive reinforcement. The goal of behavior therapy is to increase positive reinforcement by participation in pleasant activities or building assertive skills needed to elicit social rewards. The learned helplessness model (Seligman 1975) and behavioral therapy for depression (Lewinsohn 1974) support the merit of these theoretical strategies. Similarly, cognitive–behavior therapy (CBT) represents perhaps the only treatment of any type with clear evidence for efficacy in bipolar depression (see Section “Psychotherapies”).

The interpersonal theory of depression, which serves as the theoretical basis for interpersonal psychotherapy (IPT) (Klerman et al. 1984, Weissman and Klerman 1991), builds on the work of Adolph Meyer and Harry Stack Sullivan, who considered environment to play an important role in symptom development and protection from illness. Interpersonal theory proposes that depression develops most often in the context of adverse events, particularly interpersonal loss. IPT then aims at reducing symptoms by psychoeducation and subsequently by addressing problems in interpersonal relationships, primarily focusing on grief, role disputes, role transitions, and interpersonal deficits. Interpersonal factors, coupled with circadian rhythm disruption, have been hypothesized to play a role in manic-depressive disorder as well (see Section “Psychobiological Hypotheses”).

Psychoanalytic theories regarding depression find perhaps their most concise and elegant formulation in Freud’s classic Mourning and Melancholia (Freud 1924). Further development of his theories of depression is found throughout his New Introductory Lectures in Psychoanalysis (Freud 1933). For subsequent development of psychoanalytic theories of depression, the reader is referred in particular to Abraham (1927) and Fenichel (1945). As with schools of thought, psychoanalytic theory regarding mania has been much more limited than for depression. In general, psychoanalytic theories focus on mania as a less than completely successful defense against underlying depression. For instance, Dooley (1921) proposed that mania was a mechanism whereby one could ward off painful depressive thoughts. Schwartz (1961) suggested that mania, particularly its hyperactive and grandiose components, functioned as a defense against underlying emptiness and deprivation.
Fenichel (1945) also considered mania to be a response to depression. He proposed that depressive symptoms were caused by a battering superego punishing the self, while “the triumphant character of mania arises from the release of energy hitherto bound in the depressive struggle and now seeking discharge.” Nonetheless, he succinctly remarks later in a discussion of cyclicity in manic–depressive and other mood disorders: “yet it is impossible to get rid of the impression that additional purely biological factors are involved”! More recent psychoanalytic theorists have emphasized the need for revision of traditional psychoanalytic theories in the face of accumulating evidence of a biological component to major mental illnesses, including manic–depressive disorder (Cooper 1985, Kahn 1993).

**Psychobiological Hypotheses**

Successful treatment of manic–depressive disorder with medications has made the existence of a biological component of this disorder incontrovertible. Nonetheless, psychosocial factors may play prominent roles in the development of manic–depressive disorder and, once established, in its course. Several models that integrate psychological factors and biological mechanisms have been developed (Johnson and Roberts 1995).

Several examples illustrate the diversity of these proposals. As noted above, the kindling model proposed that discrete environmental stressors may be translated into enduring neurobiological changes that are responsible for mood episodes in manic–depressive disorder. Frank and colleagues (Ehlers et al. 1988, Frank et al. 1994, Swartz and Frank 2001) have proposed that the regulation of biological rhythms in persons with manic–depressive disorder may be disrupted by changes in interpersonal events. Depue (Depue et al. 1985, Depue and Iacono 1989) has proposed that mood disordered individuals, including those with manic–depressive spectrum disorders, have deficits in the regulation of biological responses to stress. Similar to cognitive theorists, Hume et al. (1988) have proposed another stress–vulnerability model specifically for manic–depressive disorder in which the threshold for commencement of mood symptoms, particularly in manic–depressive disorder, is influenced by a combination of the “perception” one has of stressful life events and a vulnerable biochemical mood regulatory system.

**Neurocognitive Factors**

A variety of deficits in cognition have been demonstrated in manic–depressive disorder, though none of these has to date been proposed to play a pathogenic role. However, it is intriguing to speculate regarding how the cognitive deficits described below might make individuals more susceptible to psychosocial stressors that have been proposed to play a pathogenic role in the illness. Further, such deficits are important in understanding the clinical picture of the disorder, and in planning treatment. In this important last regard, if individuals with the disorder have clinically relevant cognitive compromise, despite not having a formal cognitive disorder diagnosis, it is likely that their ability to manage increasingly complex treatment regimens, navigate interpersonal relationships, and maintain optimal social role function will all be compromised. That said, the same *caveats* that apply to neuroimaging and other mechanism studies of manic–depressive disorder should be kept in mind, including the difficulty in differentiating among core pathogenic factors, nonspecific effects of illness progression, correlates of comorbid disorders, and effects of treatment.

A wide variety of cognitive deficits have been demonstrated in euthymic individuals with manic–depressive disorder, including sustained attention (Clark et al. 2002, Wilder-Willis et al. 2001), working memory (Ferrier et al. 1999), visuospatial memory (Rubinsztein et al. 2000), verbal memory (van Gorp et al. 1998, Althshuler et al. 2004), declarative memory (Thompson et al. 2001, van Gorp et al. 1999), problem-solving (Scott et al. 2000), processing speed (Tham et al. 1997), verbal learning (Zubieta et al. 2001), and executive function (Ferrier et al. 1999, El Badri et al. 2001, Althshuler et al. 2004). A recent meta-analysis of cognitive function in the euthymic phase of the disorder indicated that the most prominent abnormalities are found in executive function and verbal learning, with additional deficits in verbal memory, abstraction and set-shifting, sustained attention, response inhibition, and psychomotor speed (Robinson et al. 2006).

**Social/Environmental Factors**

**Psychosocial Stressors**

The possible association of stressful life events and the onset of depression has generated substantial interest among researchers from various theoretical backgrounds (e.g., Brown et al. 1977, Brown 1989, Beck et al. 1979, Klerman et al. 1984, Perris 1984a, 1984b, 1984c, Paykel and Cooper 1992, Frank et al. 1994, Johnson and Roberts 1995). Most of the literature regarding analysis of the relationship between stressful life events and manic–depressive disorder has focused on the precipitation of episodes in established manic–depressive disorder rather than the onset of the disorder de novo. However, recently Alloy et al. (2006) extensively and thoughtfully reviewed the literature on the relationship of parenting and maltreatment as risk factors for mood disorders. They found an association between depression and an “affectionless control” style of parenting, particularly with low levels of care, with suggestive evidence for an association with manic depression as well. They propose that the link is not specific, but rather increases risk of negative cognitive styles, which then lead to “a variety of forms of internalizing psychopathology.”

There are several methodological problems that may make interpretation of life events studies difficult. Examples include recall bias in retrospective design, and in both retrospective and prospective studies include sample heterogeneity, length of time window for identification of relevant events, definition of onset of mood episode, and choice of signal event (e.g., hospitalization versus onset of episode). Further, in prospective studies, differences in attribution and recall can be significantly different depending on whether a person is interviewed for life events prior to or after the index episode has commenced.

Data on the relationship between life events and the course of manic–depressive disorder have recently been extensively reviewed by Johnson (2005). An association of episode onset with severe adverse life events, typically major losses, on symptoms or episodes has been fairly consistent across studies. This relationship appears to
obtain for depressive but not manic episodes, though many depressive episodes have no identifiable stressor. There is less evidence that schedule-disrupting events trigger either type of episode, aside from sleep disruption being associated with mania (e.g., Colombo et al. 1999). Intriguingly, there is a small literature indicating that goal attainment may be associated with manic episodes, consistent with the model that individuals with manic–depressive disorder have (at times) heightened response to environmental rewards.

Integrating Assessment and Treatment: The Biopsychosocial Approach

While the evidence reviewed above in Section “Neurobiologic Factors” and below in Section “Antimanic, Antidepressants, and ‘Mood Stabilizers’” indicates that there is a substantial biological substrate for manic–depressive disorder, we also know that the illness is not fully genetically determined, and that its etiology and course are not meaningfully explainable in solely biological terms. Moreover, astute clinicians realize that psychosocial factors must be taken into account when planning any type of chronic illness treatment. Therefore, a nonreductionistic and biopsychosocial approach to the disorder, as Engel (1977) proposed for all medical illnesses, will likely serve us best as clinicians, educators, and researchers. Accordingly, Section “Treatment” on treatment deals with an equal level of attention to both pharmacologic and psychosocial interventions for this illness.

Treatment

Treatment Goals

General Considerations

Traditionally, treatment for manic–depressive disorder has been categorized as acute versus prophylaxis, or maintenance, i.e., treatment geared toward resolution of a specific episode versus continued treatment to prevent further symptoms.

In a complementary conceptualization, treatment can be focused on improving clinical outcome (episodes and symptoms) or functional outcome (social and occupational function and health-related quality of life). Although this categorization appears straightforward, clinical practice reveals many subtleties. For instance, it is erroneous to assume that clinical outcome is the domain of pharmacotherapy and that functional outcome is the domain of psychotherapy. In actuality, most psychotherapies by design focus on reducing symptoms. Likewise, pharmacotherapeutic stabilization of symptoms clearly contributes to improved role function. Further, treatments that improve one domain may cause decrements in another. For instance, effective maintenance treatment with lithium may come at the cost of hand tremor, decrements in another. Further, treatments that improve one domain may cause symptoms. Likewise, pharmacotherapeutic stabilization of symptoms clearly contributes to improved role function. Further, treatments that improve one domain may cause decrements in another.

What is the goal of treatment? As articulated in The President’s New Freedom Commission for mental health, the goal of treatment is recovery, which is described as “a process of positive adaptation to illness and disability, linked strongly to self-awareness and a sense of empowerment” and, after Anthony (1993), “a way of living a satisfying, hopeful, and contributing life even with the limitations caused by illness” (Hogan 2003).

Understanding Evidence-Based Medicine

One of the functions of a textbook is to synthesize and present relevant scientific data in a concise and easily accessible manner. Another is to provide the context and underpinnings of such data. In the service of this latter aim, this treatment section is introduced, as in the last edition, with a brief review of evidence-based methods of evaluating the available scientific data, including both the strengths and weaknesses of the evidence on which we base clinical and sometimes policy decision-making.

Levels of Evidence

A major advance in the last 20 years in medicine has been development of quantitative and qualitative tools to assess the quality of data that underlie our treatment decisions, typically considered under the rubric of “evidence-based medicine.” For instance, quantitative techniques such as meta-analysis provide numeric conclusions with regard to significance of similar interventions in diverse studies (Irwig et al. 1994). More quantitative, yet standardized, techniques of evidence-based medicine (EBWG 1992, Chalmers 1993, ACC/AHA 1996) have been used in reviewing and summarizing treatment interventions in medicine and more recently in mental health. Briefly, these techniques consist in comprehensively identifying relevant data-based articles, summarizing their methods and conclusions, and then in a standardized quantitative or qualitative fashion rating the scientific quality of the evidence based on the rigor of their methodology.

In the 1980s, the US Agency for Healthcare Research and Quality (AHRQ) (formerly the Agency for Health Care Policy and Research; AHCPR) developed guidelines for a wide variety of medical, surgical, and mental health conditions including the identification and treatment of depression in primary care (AHCPR 1993). Similar evidence-based techniques of one type or another have also served as the basis for bipolar guidelines from a variety of professional groups including, for example, the American Psychiatric Association (2002), US Department of Veterans Affairs (VA) (e.g., VHA 1997, Bauer et al. 1999), the Canadian Psychiatric Association (Haslam et al. 1997), the Texas Department of Mental Health and Mental Retardation (Gilbert et al. 1998, Rush et al. 1999), the British Association for Psychopharmacology (Goodwin et al. 2003), the World Federation of Societies of Biological Psychiatry (e.g., Grunze et al. 2004) and the Canadian Network for Mood and Anxiety Treatments (Yatham et al. 2000). However, not all bipolar guidelines are evidence based in this sense, but rather are based on surveys of experts’ opinions (e.g., Kahn et al. 1997, Sachs et al. 2000).

The AHCPR developed a hierarchical system for categorizing evidence according to the scientific quality (internal validity) of the studies (Table 67–11), a variant of which has been used by most guidelines for assessing evidence. Some guidelines also use a system by which the guideline authors utilize the evidence to arrive at a “strength of recommendation,” which is also based implicitly on quality of the underlying evidence (e.g., American Psychiatric Association 2002).
The astute clinician will therefore bring neither uncritical enthusiasm nor undue cynicism to the evidence base for treatment of manic–depressive disorder. Rather, an awareness of the potential for circumstantial, and perhaps at times purposeful (e.g., Angell 2004), bias is in order—as has been formally recognized by leading journal editors (e.g., Lewis et al. 2006, Freedman et al. 2006). Given the complexities socioeconomic nexus from which scientific data derive, one might do well to adapt an old saying: **Caveat lector**—Let the reader beware (Bauer 2006).

### Somatic Treatments

**Antimanics, Antidepressants, and “Mood Stabilizers”**

**Mood Stabilizers: The “2 × 2” Definition**

The term “mood stabilizer” is not recognized by the US Food and Drug Administration (FDA). The term is used loosely among both clinicians and scientists, leading to some confusion. It stands to reason that an agent could be considered a mood stabilizer for manic–depressive disorder if it has efficacy in four key roles in its treatment: (a) treatment of acute manic symptoms, (b) treatment of acute depressive symptoms, (c) prophylaxis of manic symptoms, and (d) prophylaxis of depressive symptoms (alternative terms for prophylaxis include prevention, maintenance treatment). We (Bauer and Mitchner 2004) and others (Calabrese et al. 1999) have proposed this definition, while at other times some have argued for a looser definition, which applies the term to any agent that has efficacy in any one of those roles while not worsening other aspects of the disorder (Sachs 1996, Bowden 1998, Ketter and Calabrese 2002).

**Limitations: The Pyramid of Evidence Quality**

Understanding published data according to levels of quality is clearly a conceptual advance of great importance—data from a case series are clearly not the same as data from Class A randomized controlled trial (RCT). However, one of the limitations of the evidence base for manic–depressive disorder, and one suspects for disorders in general, is that the RCT “jewel in the crown” of evidence-based medicine represents only a small fraction of the available data—far more data derive from Class B and C studies (e.g., Bauer and Mitchner 2004).

**Limitations: The Efficacy–Effectiveness Gap**

Moreover, the grading of evidence is based solely on characteristics related to internal validity, the scientific structure of the protocol itself. A complementary concern is that of external validity, the applicability of findings to a population of more general interest. The US Institute of Medicine recognized as long ago as 1985 (Institute of Medicine 1985) that there is a persistent gap between the impact of treatments predicted by highly controlled trials (efficacy) and the actual performance of such treatments in general practice (effectiveness). They proposed that this “efficacy–effectiveness gap” is in part due to the exclusion of “complicated” subjects from clinical trials (e.g., for manic–depressive disorder, those with substance abuse, personality disorders, or medical problems) and those unwilling to risk exposure to placebo. Another likely contributor is variation in provider attitudes and capabilities, and a third is system characteristics that support or impede optimal care in general practice. One can see that, in efficacy trials to establish the impact of a new intervention, it is reasonable to assess impact under optimal conditions; however this same exclusivity and careful control also limit the relevance of such studies in the general clinical setting. Recognizing this, a number of recent clinical trials, considered variously under the related concepts of “effectiveness trials” (Wells 1999, Bauer et al. 2001a) or “practical clinical trials” (e.g., March et al. 2005) have sought to address this gap, balancing issues of internal and external validity to more cogently inform clinical practice for manic–depressive disorder (e.g., Geddes et al. 2002, Sachs et al. 2003, Bauer et al. 2006a, 2006b, Simon et al. 2006), as is also being done for such other disorders as depression (e.g., Fava et al. 2003) and schizophrenia (e.g., Stroup et al. 2003).

**Limitations: The Question of Bias in the Evidence Base**

“Bias” is a hot-button word that raises the specter of scientific misconduct, or worse. However, bias is best understood as a compromise in internal validity within or across studies, which may be purposeful or not. Several studies have demonstrated evidence of bias in several areas in peer-reviewed literature (e.g., Dickersin 1997, Montori and Guyatt 2000). While we are not aware of publication bias in the literature on treatment of manic–depressive disorder, there is such evidence in other areas of psychopharmacology. For instance, meta-analyses of antidepressant and anxiolytic efficacy, based on predominantly published data, are regularly positive (www.cochrane.org). However, analysis of the FDA Summary Basis of Approval Reports for approved antidepressants and anxiolytics—which reflect all studies, published and unpublished, submitted to the FDA—indicates that the majority of such studies are actually negative (Khan et al. 2002). Of additional concern, there appears to be a sponsorship bias in which industry-sponsored studies that show evidence for efficacy of a proprietary agent are more likely to be published than those that show no efficacy (Davidson 1986, Rochon et al. 1994, Djulbegovic et al. 2000), as has also been demonstrated in mental health treatment research (Kelly et al. 2006), pharmacoeconomic studies (Baker et al. 2003), and meta-analyses (Jorgensen et al. 2006).

Source: Adapted from HCPR (1993).
Although it is clear that a single agent suffices to stabilize manic-depressive disorder in only a minority of individuals (e.g., Sachs et al. 1994b, Unützer et al. 1998), adopting the more stringent definition both focuses our search for new interventions on all phases of the disorder and also leads to a conceptual approach that clarifies our evaluation of evidence. This approach leads to arraying the evidence according to a conceptual 2 × 2 table (mania/depression, acute/prophylaxis), in which agents used in manic–depressive disorder can be listed in any or all of the four boxes in the table in which they have proven efficacy. According to this schema, an agent would be categorized as a mood stabilizer if it can be listed as having efficacy in each of the four boxes.

**Summarizing the Class A Evidence**

We have conducted an exhaustive review of the literature on psychopharmacologic agents used in manic–depressive disorder and evaluated them against this “2 × 2” definition, as detailed elsewhere (Bauer and Mitchner 2004) and more recently updated to include combination treatments (Bauer 2005). Briefly, we identified all Class A double-blind controlled trials for acute (hypo)mania, acute depression, prevention of (hypo)mania, and prevention of depression. We considered an agent to be efficacious for each of these roles if it met the “FDA-like” criterion of having at least two published placebo-controlled trials indicating efficacy. Note that we reviewed only studies published in the peer-reviewed literature, not unpublished studies.

Tables 67–12 through 67–14 summarize this review, updated here with studies published through December 2006. These tables include only those agents with at least two double-blind controlled trials, using either placebo or an active comparator, either in a parallel groups design or a within-subjects, on–off–on (ABA) design. Note also that negative studies are also listed for these agents, with the study preceded by a “-”.

In summary fashion, Table 67–15 summarizes these trials based on the 2 × 2 definition of a mood stabilizer. As can be seen, a substantial number of agents meet criteria as acute antimanic agents, while only lithium meets criteria for acute depression. The paucity of efficacious agents for bipolar depression is striking, though a pooled meta-analysis of 12 Class A antidepressant trials supports overall efficacy of the class, without difference among types of antidepressants (Gijsman et al. 2004). Lithium and lamotrigine meet criteria for prophylaxis. Note that most studies assessed relapse to any episode rather than specifically mania or depression, while lithium has also been shown in two studies to prevent relapse specifically to mania.

**Some Additional Considerations**

The vast majority of studies of efficacy against manic symptoms comes from study of mania rather than hypomania. The latter is treated predominantly by logical extension.

Evidence is scarce concerning efficacy of specific agents for acute depressive episodes, which appears to be a particularly difficult syndrome to treat pharmacologically. Most treatment is undertaken by extension from treatment experience in unipolar depression. A comprehensive discussion of evidence for efficacy of various antidepressants in unipolar depression can be found in Chapter 101 in this book. The particularly important issue of how long and how aggressively to treat bipolar depression with antidepressants is of sufficient importance to address in a separate section (see Section “Balancing Beneficial and Unwanted Effects of Medications”).

While lithium has the most extensive support for prophylaxis, it is also notable that strong case-control data across 10,000s of patient-years support an antisuicide effect (e.g., Baldessarini et al. 2003, Goodwin et al. 2003, Ernst and Goldberg 2004). Interestingly, this effect appears to be independent of lithium’s effect on mood (e.g., Hanus and Zapletalek 1984, Lepkifker et al. 1985, Ahrens and Muller-Oerlinghausen 2001); moreover, lithium may also be associated with reduced all-cause mortality (Tsai et al. 2005).

Additional issues in prophylaxis of manic–depressive disorder deserve comment. When is lifetime, or at least long-term, prophylaxis warranted? After one manic episode? One hypomanic episode? One depressive episode with a strong family history of manic–depressive disorder? There is insufficient empirical evidence with which to make strong recommendations, although a creative study by Zarin and Pass (1987) using computer-based modeling investigated tradeoffs of treatment versus observation based on costs and benefits of recurrence risks and drug side effects under several strategies. In clinical practice without clear guidelines, such decisions need to take into account the capability of the patient and family in reporting symptoms, rapidity of onset of episodes, episode severity, and associated morbidity. Clearly, the risks of a wait-and-see strategy would be different in a person who had a psychotic manic episode than in a person who had mild hypomania.

Can maintenance, or prophylaxis, medications ever be discontinued? Again, there are no solid data on which to base this decision. However, if lithium discontinuation is contemplated, there is evidence that rapid discontinuation (in less than 2 weeks) is more likely to result in relapse than slow taper (2–4 weeks), with relapse rates higher in type I than in type II patients (Faedda et al. 1993, Suppes et al. 1993). In type I patients, relapse rates for rapid discontinuation versus slow taper were, respectively, 96 and 73%, whereas in type II patients they were 91 and 33% (Faedda et al. 1993).

**Combination Strategies**

As noted above, combination strategies are the rule rather than the exception in clinical practice (e.g., Sachs et al. 1994b, Unützer et al. 1998). Table 67–16 summarizes the Class A placebo-controlled trials of combination strategies for manic–depressive disorder.

**A Simple Treatment Algorithm for Manic–Depressive Disorder**

A treatment algorithm for refractory manic–depressive disorder, including strategies to deal with rapid cycling is found in Figure 67–2. It is derived from clinical practice guidelines from the USVA and used in a multisite collaborative care management trial for manic–depressive disorder (Bauer et al. 2006a, 2006b). By design, the algorithm primarily specifies drug classes rather than individual agents. This allows the choice of specific agent to be chosen collaboratively by the provider and the patient based on efficacy data combined with patient preference (see also Sections “Balancing Beneficial and Unwanted Effects of Medications” and “Treatment-Refractory Patients”). In a multisite proof-of-concept study, the use of the algorithm was significantly associated with
increased intensity of mood-specific pharmacotherapy (Bauer 2001a). The entry point for this algorithm is the occurrence of any major mood episode (depression, hypomania, mania, or mixed episode) in an unmedicated patient. Patients with recurrence on medications may enter the algorithm at the appropriate point along the flow diagram. For simplicity of presentation, only depressive and cycling outcomes are illustrated. This is because depressive episodes are more common than manic or hypomaniac episodes, and all but the most refractory of the latter episodes are relatively easily treated by the addition (or resumption) of lithium or anticonvulsants or the use of neuroleptics, as summarized above.

### Balancing Beneficial and Unwanted Effects of Medications

All psychotropic medications have side effects. Some side effects may actually be desirable (e.g., sedation with some antidepressants in persons with prominent insomnia), and specific medications are often chosen on the basis of desired side effects. However, side effects usually represent factors that decrease a patient's quality of life and compromise adherence.

Extensive reviews of side effects of the agents most commonly encountered in the treatment of manic-depressive disorder are available elsewhere in this textbook (Chapters 101, 102, and 103), in a variety of texts.
Section VI • Disorders

(e.g., Bauer 2003a, Schatzberg et al. 2003, Marangell and Martinez 2006), and in electronic references for desktop and hand-held computers. Several excellent review articles have summarized side effects of lithium (Gitlin et al. 1989, Goodwin and Jamison 1990, pp 701–709) and the various anticonvulsants (Swann 2001) including carbamazepine (Ketter and Post 1994) and divalproex (Keck et al. 1994), and lamotrigine (Botts and Raskind 1999).

A brief overview of the most frequent or important side effects of lithium, carbamazepine, and valproic acid is found in Tables 67–17a–c. Note that some side effects may be encountered at any serum level of the drug, even within the therapeutic range. Some side effects may be dose related even within that range and may respond to dosage reduction. Others are more idiosyncratic and require other management, as detailed in a subsequent section. Note that

| **Prophylaxis** |           |
| Imipramine → lithium | Quitkin et al. (1981) |
| High-dose thyroxine → treatment as usual (in rapid cycling) | Bauer et al. (1990) |
| Divalproex → lithium | Solomon et al. (1997) |
| Omega-3 fatty acids → treatment as usual | Stoll et al. (1999) |
| Magnesium → verapamil | Giannini et al. (2000) |
| Gabapentin → lithium or divalproex or Carbamazepine | Vieta et al. (2006) |

*Both lithium and lamotrigine are supported by at least two placebo-controlled Class A trials for prophylaxis that measured time to relapse to either mania or depression. Lithium is also supported by two such trials for relapse specifically to mania and one for relapse specifically to depression plus one trial versus active comparator for relapse specifically to depression (see Table 67–12).*

Not all laboratory findings represent pathological processes that are associated with or presage morbidity for the patient; that is, not all are clinically significant.

Note also that the concept of the “therapeutic level” is not as straightforward as we would like to assume. The lower limit is usually established by the lowest level necessary for therapeutic effect, whereas the upper limit is set by the lowest level associated with regular, significant toxicity. This range is never established with complete precision. For some medications such as lithium, the therapeutic window is actually quite narrow, with toxic effects developing with some regularity after the upper limit of the therapeutic range is surpassed and with serious toxicity developing at only modestly higher serum levels. As a further complication, for many persons the minimum level of lithium for good response may be substantially above the 0.5–0.8 mEq/L that is usually set as the lower therapeutic limit, but this is reached only at the cost of increased incidence of side effects (Gelenberg et al. 1989). On the other hand, for divalproex, the upper limit of the therapeutic range for mood stabilization may actually be 125 mg/dL rather than the listed range of 100 mg/dL usually accepted for antiepileptic effect, and this level is often reached without undue side effects (Keck et al. 1994).

Thus established therapeutic levels should be used as important guidelines, and exceeding therapeutic levels should be done only with careful monitoring. However, one must not be falsely reassured that reaching the lower level of a therapeutic range is equally effective for all patients, while taking with a grain of salt the upper limits of the therapeutic range for drugs with a wider therapeutic window.

Another important issue to consider is drug–drug interactions, which may lead to side effects (see Bauer [2003] for a comprehensive review). Most commonly the locus of such interactions is the hepatic microsomal P-450 metabolic system, which inactivates drugs and other exogenous substances, and for which psychotropic drugs are often substrates, inhibitors, or inducers. However, other drug interactions must also be kept in mind. For example, addition of thiazide diuretics, or nonsteroidal anti-inflammatory agents, the latter available over the counter, is a common reason for increase in lithium level and development of toxicity based on changes in renal handling of lithium. Note also that toxic drug–drug interactions may not be reflected in an increased serum level if the main interaction is displacement of protein-bound drug. Because free drug concentrations are usually 1–10% of total serum drug, a displacement of even 50% of bound drug may be associated with negligible if any changes in total serum level. However, since both therapeutic and toxic effects are due to free, not bound, drug, unwanted side effects may develop despite total drug levels measured in the therapeutic range.

### Balancing Risks and Benefits of Antidepressant Treatment

Traditionally over the past generation, the teaching has been to use antidepressants in bipolar depression gingerly, only for the shortest time and lowest dose possible; this is based on data indicating an association between antidepressant use and emergence of manic symptoms or rapid cycling (e.g., El-Mallakh and Karippot 2002). Estimate of the risk of antidepressant-induced (hypo)mania, typically defined as symptom emergence within 2 weeks of the initiation of antidepressants, range from 9 to 40% (e.g., Post et al. 2001, Goldberg and Whiteside 2002, Post et al. 2006), though a meta-analysis of 12 Class A trials found no difference in...
switch rate versus placebo (Gijsman et al. 2004). The risk appears to be higher with antidepressants that affect both catecholaminergic and serotonergic neurotransmission than those that affect only the latter (e.g., Peet 1994, Gijsman et al. 2004, Mundo et al. 2006, Post et al. 2006), while evidence is split regarding whether bupropion is relatively safer (Sachs et al. 1994a, Post et al. 2006) or not (Joffe et al. 2002). This risk is not fully counterbalanced by treatment with antimanic agents (e.g., Post et al. 2001) though such medications (Mundo et al. 2006), perhaps especially lithium (Henry et al. 2001), may provide added protection.

However, counterbalancing this risk is the robust finding across more than a dozen studies that continuing

*Typically during first 1–6 months of treatment; for lamotrigine, related to rate of dose increase.
depression is the strongest predictor of poor functional outcome (reviewed in Bauer et al. 2001a) and poor self-reported quality of life (e.g., Vojta et al. 2001, Zhang et al. 2006); not surprisingly, continued depression is also a risk factor for relapse (reviewed in Altman et al. 2006) and suicide. Moreover, in contrast to findings in adolescent depression and anxiety disorders, treatment with antidepressants does not appear to increase suicidality in individuals with manic-depressive disorder (Bauer et al. 2006c, McElroy et al. 2006b). In addition, there is an accumulating evidence base indicating that cessation of antidepressants increases risk for bipolar depressive relapse (e.g., Altshuler et al. 2003, Fu et al. 2006).

Thus prior practice must be reevaluated, and we should give renewed consideration to aggressive, long-term treatment of individuals with bipolar depression with antidepressants. Careful monitoring for the emergence of manic symptoms must, of course, be part of this treatment, and most guidelines recommend cotreatment with antimanic agents.

Guiding Principles for Managing Side Effects
As noted previously, some side effects may be desirable. However, in many cases they are impediments to treatment, frequently of sufficient importance to lead to nonadherence (Jamison et al. 1979). As clinicians, however, we might reframe nonadherence not as a patient characteristic but rather as a characteristic of the clinician–patient dyad (Sajatovic et al. 2006); that is, nonadherence is most appropriately considered as an instance of “insufficient provider–patient cost-benefit analysis.” Stressing adherence when a person suffers from significant side effects is usually much less effective than working to set appropriate expectations of the patient and to find a regimen of minimal toxicity. Goodwin and Jamison’s (1990, p 672) point that managing side effects is as much psychotherapeutic as medical is well taken in this regard, and has been a key component of some psychosocial interventions for this disorder (e.g., Bauer and McBride 2003).

Nonetheless, the astute psychiatrist does have several strategies available to improve patients’ tolerance of medications. First, dose reduction may be achieved without compromising efficacy in some patients. Some side effects, such as lithium-induced nausea, usually respond well to this, whereas others, such as lithium-induced memory loss, improve less reliably. Second, simple changes in preparation may be helpful, such as using enteric-coated lithium. Uncoated valproic acid causes nausea so frequently that only the coated forms are routinely used; however, the pediatric “sprinkle” preparation may be of some benefit in persons with nausea even with enteric-coated valproic acid. Third, changing the administration schedule may ameliorate side effects. Commonsense strategies such as taking

nausea-inducing medications after a meal should not be overlooked. Single daily dosing of lithium, carbamazepine, or valproic acid may decrease daytime sedation without compromising efficacy. For more obscure reasons, single daily dosing of lithium appears to decrease polyuria quite effectively (Bowen et al. 1991). Fourth, addition of medications to counteract side effects can sometimes be the only way to continue treatment. Addition of beta-blockers can reduce lithium- or valproic acid-induced tremors. Judicious use of thiazide diuretics, often in conjunction with potassium-sparing diuretics or potassium supplements, can reduce lithium-induced polyuria. Finally, change to another drug may be the only alternative. This is clearly indicated in the case of serious allergic reactions. Polypharmacy should be avoided wherever possible.

**Psychosocial Treatments**

Since the first edition of this textbook one of the fastest moving areas of research in manic–depressive disorder has been the development of psychosocial interventions. Such interventions have been studied almost exclusively in the context of ongoing medication management, rather than as a substitute for psychopharmacology. The field has advanced quickly enough that now space allows review only of Class A controlled trials of such interventions, and the reader is referred to the prior edition for review of the breadth of interventions that have been studied under less controlled conditions (Bauer 2003b).

Another aspect of the dynamism of this area is the application of chronic care models to manic–depressive disorder. While there is some overlap conceptually and generationally with psychotherapy, the interventions are sufficiently distinct to warrant separate description.

**Psychotherapies**

Class A studies of psychotherapy for manic–depressive disorder, all of which added psychotherapy to reasonable pharmacotherapeutic regimens, are summarized in Table 67–18. Several differences are evident in comparison to the pharmacotherapy studies reviewed above. Most psychotherapy studies investigated outcome or process measures over time, rather than response of acute episodes, so the table is divided into relatively shorter versus longer term studies rather than strictly acute versus prophylaxis as in medication trials. Such study designs reflect the expectation that psychotherapy acts via mechanisms that involve relearning and behavior change, and that such mechanisms take time. Additionally, the variety of outcome measures tends to be more heterogeneous, reflecting the breadth of outcomes hypothesized to be responsive to psychotherapeutic interventions. Studies also tend to reflect assessment of incremental or ongoing change over time rather than time to relapse, which some have proposed is more relevant to cognitive psychotherapy than those who are higher functioning (Scott 2005, Scott 2006a, 2006b), and that family therapy cannot be done on those who do not have families. Thus efficacy versus effectiveness considerations (see Section “Understanding Evidence-Based Medicine”) are at least as prominent with psychotherapy studies as with other interventions, and enhancing such treatments to engage and improve outcome for more severely ill individuals clearly must be a focus of future work. In this regard, the relatively short-term group intervention study of individuals with manic–depressive disorder and comorbid substance use disorders is promising (Weiss et al. 2007).

**Collaborative Chronic Care Models for Manic–Depressive Disorder**

Chronic care models (CCMs) have been applied to management of chronic medical illnesses, addressing which are inadequately treated, despite the availability of efficacious medications (Von Korff et al. 1997, Wagner 2000, Bodenheimer et al. 2002a–2002c). The central focus of CCMs, which are based on principles of social learning and self-regulation theories (Von Korff et al. 1997), is to reorganize medical care to support an effective partnership between clinicians and patients to improve outcomes relevant to patients (Bodenheimer et al. 2002a). CCMs typically include components to enhance patient self-management skills, facilitate information flow to providers, support provider decision-making via expert guidance through guidelines or consultation, and redesign work roles to emphasize anticipatory rather than reactive care. They are clinic based without mobile treatment or community outreach components. Substantial evidence indicates that CCMs improve process and outcome measures for a variety of chronic medical illnesses (Bodenheimer et al. 2002b, 2002c) and for depression treated in primary care (Badamgarav et al. 2003) and may be cost-effective (Simon et al. 2001).

Recently, two multisite RCTs totaling over 700 subjects (Bauer et al. 2006a, 2006b, Simon et al. 2005, 2006) have shown that CCMs can also improve clinical and functional outcome and process measures in manic–depressive disorder, and at minimal to no net cost (see Table 67–18). Importantly, both these trials were constructed as effectiveness trials (see Section “General Considerations”), enrolling unselected or severely ill patients.

Thus CCMs likely have a role in optimizing outcome for individuals with manic–depressive disorder, including those with severe illness. Based on these studies, at least one major practice guideline has endorsed their use in this disorder (Yatham et al. 2006). Notably, CCMs involve psychotherapeutic components, and psychotherapeutic interventions involve some (usually implicit) care coordination; thus both may be considered along a continuum of psychosocial interventions.

It is notable from Table 67–18 that, in distinction to psychopharmacological studies, several interventions have demonstrated reduced time depressed or depressive relapse rate. Several interventions have also shown improvement in manic symptoms or relapse. Importantly, improved social role function has also been demonstrated with several psychotherapies.

Optimism for combined psychotherapy–pharmacotherapy is clearly warranted, but is tempered somewhat by evidence that more ill patients tend to do less well in at least cognitive psychotherapy than those who are higher functioning (Scott 2005, Scott 2006a, 2006b), and that family therapy cannot be done on those who do not have families. Thus efficacy versus effectiveness considerations (see Section “Understanding Evidence-Based Medicine”) are at least as prominent with psychotherapy studies as with other interventions, and enhancing such treatments to engage and improve outcome for more severely ill individuals clearly must be a focus of future work. In this regard, the relatively short-term group intervention study of individuals with manic–depressive disorder and comorbid substance use disorders is promising (Weiss et al. 2007).

*Each row reflects a single study, sometimes reported in more than one article in which case multiple citations are listed for that row; TAU, treatment as usual.
CCMs provide a care-organization platform through which medications and psychotherapies may be more effectively delivered.

**Issues in the Clinician–Patient Relationship**

The most critical issue in establishing the clinician–patient relationship is coming to a shared understanding that manic-depressive disorder is a chronic condition that will require ongoing, anticipatory, and collaborative management. This is a key tenet of CCMs for medical illnesses (e.g., Von Korff et al. 1997, Wagner et al. 1996), and has also been a critical component of such models for manic–depressive disorder (e.g., Bauer and McBride 2003, Bauer et al. 2006a). As detailed in these resources, the clinician–patient relationship must include education to enhance self-management skills and adequate access and continuity of care—timely access can often prevent hospitalization for mania if new onset symptoms can be treated early, and can minimize nonadherence due to medication side effects.

The collaborative stance that this approach entails goes beyond paternalistic ("Do as I say and you'll get better") and maternalistic ("I can fix your problems with...support/psychotherapy/pills/etc.") approaches to care. Rather, the collaborative stance is better illustrated as a "coach–athlete" relationship in which the patient is the one in competition with the illness and the clinician, standing on the sidelines of the illness, provides specific technical assistance. Some have cast this as "The patient is the values expert, the clinician is the technical expert," or "The clinician is the expert in disease in general and the patient is the expert in their specific case." Regardless of analogy, the collaborative approach stresses activation of patient motivations, priorities, and skills in the service of identifying needs and priorities that can be addressed by the clinician's technical skill. There is empirical evidence that individuals with manic depression prefer such approaches (e.g., Ludman et al. 2002, Berk et al. 2004) and such patient-activating approaches have begun to be incorporated into clinical practice guidelines (e.g., Yatham and Kennedy 2005).

It should also be noted that patients often come to treatment ambivalent about recognizing their illness or accepting appropriate treatment. This should be treated as the norm rather than the exception, as it is for most illnesses and behavioral medicine situations; that is, among "stages of change," few individuals are consistently at the action stage; most are contemplative or even precontemplative. In such common situations we have found motivational interviewing techniques, which have evidence-based support for substance use disorders and behavioral medicine (e.g., Miller and Rollnick 2002, Rubak et al. 2005), also to be helpful in resolving ambivalence in manic–depressive disorder as well.

**Treatment-Refractory Patients**

In a disorder that is characterized by a relapsing course, often with interepisode residual symptoms, typically with ongoing functional deficits, and usually requiring multiple medications to achieve even this status, what is the meaning of "refractory"? There is no widely accepted definition, as there is for individual major depressive episodes. Accordingly, while there have been a large number of combination studies after individuals failed to respond to mono- or dual therapy (see Section "Combination Strategies"), there have been only a few studies that investigated individuals judged a priori to be "refractory." Refractory bipolar depressive episodes had very low response rates in a RCT of added lamotrigine, risperidone, or inositol (Nierenberg et al. 2006). Among those with rapid cycling, a parallel group placebo-controlled trial of lamotrigine revealed mixed results (Calabrese et al. 2000), while a case series and very small on/off/on placebo-controlled trial of high-dose thyroxine revealed some improvement in refractory rapid cycling (Bauer and Whybrow 1990). A controlled trial of added clozapine versus maintenance treatment as usual indicated some benefit in those with a recurring course and a history of mania (Suppes et al. 1999).

A complementary approach to understanding refractoriness is to consider characteristics that coexist with the illness that increase difficulty in treatment. Such contributors include comorbid psychiatric disorders, comorbid medical disorders that limit treatment choice or contribute to depressive symptoms and functional deficits, and nonadherence. Additionally, when an individual does not respond to a variety of treatments, the diagnosis itself should be reconsidered, and investigation undertaken in particular for medical and substance-related causes of the symptoms.

**Special Features Influencing Treatment**

**Treatment of Comorbid Disorders**

As noted in Sections “Medical Precipitants of Manic or Depressive Symptoms” and “Medical Comorbidity,” medical disorders or treatments may cause mood episodes, either de novo or in the course of already established manic–depressive disorder. Regarding comorbid psychiatric disorders, the choice of approach to management may be driven by a variety of implicit assumptions. Psychiatrists may assume that the comorbid disorder is caused by manic–depressive disorder and consequently believe that treatment of the manic–depressive disorder will lead to resolution of the comorbidity. Others may assume that the mood instability of manic–depressive disorder is due to the comorbid illness, such as alcohol or drug intoxication or withdrawal, or intrapsychic or psychophysiological effects of prior trauma.

It stands to reason, rather, that parallel (simultaneous) treatment is preferable to sequential treatment (treating one disorder until resolution and then attending to the other), as the prognosis of manic–depressive disorder is worse when complicated by substance use (Himmelhoch et al. 1976, Himmelhoch 1979) and the course of alcoholism is worse when complicated by mood disorders (Rounsaville et al. 1987).

It is also likely that the highly confrontative approaches of some traditional substance dependence treatment programs will not likely serve the needs of often highly impaired depressed or manic persons. Similarly, the presence of anxiety disorders is associated with worse outcome (e.g., Simons et al. 2004b, Bauer et al. 2005a). Among RCTs for those with comorbid substance disorders, we are aware only of the integrated group psychotherapy intervention of Weiss et al. (2007), and a placebo-controlled trial of divalproex in those with comorbid alcohol dependence (Salloum et al. 2005); in this latter study divalproex reduced alcohol consumption but had no mood effects over 24 weeks. We are as yet aware of no interventions developed specifically for individuals with comorbid anxiety disorders.
Treatment of Manic–Depressive Disorder Across the Life Cycle

**Childhood and Adolescence**

Childhood and adolescence represent particular challenges for assessment, and several recent detailed reviews have recently appeared (e.g., Danielyan and Kowatch 2005, Axelson et al. 2006, Kyte et al. 2006, Strober et al. 2006). Diagnostic criteria from adults have been applied to children and adolescents, though the degree to which the syndrome is the same across ages is open to question (e.g., Biederman et al. 2004, Kowatch et al. 2005); interestingly, over 80% of youth may present with elevated rather than irritable mood. Moreover, assessment is made more difficult by overlap or comorbidity with ADHD (Kim and Miklowitz 2002, Biederman et al. 2004), anxiety disorders (Dineen Wagner 2006) and conduct disorder (Kim and Miklowitz 2002, Kyte et al. 2006). Rates of ADHD as high as 87% have been described (e.g., Biederman et al. 1999, Geller et al. 2000, Singh et al. 2006), though much lower lifetime rates in community samples of adolescents with manic–depressive disorder have been reported (11%; Lewinsohn et al. 1995). Rates of anxiety disorder range from 14 to 54% (Biederman et al. 1999, Findling et al. 2001) Rates of conduct disorder (12–41%) and oppositional-defiant disorder (46–86%) are also substantial (Biederman et al. 1999, Findling et al. 2001, Tillman et al. 2003, Axelson et al. 2006). Little is known about long-term course or outcome of manic–depressive disorder in youth (Strober et al. 2006).

Treatment is undertaken mainly by extension from treatment of adults, substantiated with open trials in youth of, for example, lithium (Kowatch et al. 2000, Kafantaris et al. 2003), carbamazepine (Kowatch et al. 2000), divalproex (Kowatch et al. 2000, Wagner et al. 2002), various antipsychotics (e.g., Frazier et al. 2001, Kafantaris et al. 2001), and cognitive–behavioral therapy (Feeny et al. 2006). Combination treatment appears to be common, as it is in adults (Kowatch et al. 2003).

Not surprisingly, there are far fewer RCTs than in adults, though some data support the utility of lithium (Kafantaris et al. 2004), divalproex (Findling et al. 2005), and quetiapine (Delbello et al. 2002 and 2006). Oxcarbazepine was found to be no different than placebo (Wagner et al. 2006), and data on topiramate are inconclusive (Delbello et al. 2005). Use of amphetamine in children with comorbid ADHD improved ADHD without worsening manic symptoms (Scheffer et al. 2005). Among psychosocial interventions, RCT data support the use of multi-family group and individual family psychoeducation (Fristad 2006) in children as well as family-focused therapy for adolescents (Miklowitz et al. 2004).

**Pregnancy**

The complexities of treating manic–depressive disorder during pregnancy and breastfeeding have recently been extensively reviewed (e.g., Yonkers et al. 2004, Gentile 2006). There is some evidence that lithium may be teratogenic, associated with increased rates of cardiac abnormalities (Weinstein and Goldfield 1975) although this risk may be overestimated (Cohen et al. 1994). Divalproex and perhaps carbamazepine (Robert and Guibaud 1983, Delgado-Escueta and Janz 1992, Scolnik et al. 1994) have been associated with neural tube defects (Robert and Guibaud 1983), leaving the neuroleptics, antidepressants, and ECT as the preferable management strategies during pregnancy, particularly during the first trimester. It should be kept in mind, however, that treatment decisions are based on risk, not certainty: Risk of fetal malformation, parental attitude toward raising children with birth defects, severity of illness, and ease of management with alternative therapies all need to be considered in conjunction with the woman and her partner.

It should also be noted that there may be some relationship between manic–depressive disorder and both postpartum depression and postpartum psychosis. These syndromes are reviewed in Chapter 119.

**Older Adults**

Aging also presents certain treatment complexities. Several extensive references have recently appeared reviewing issues in clinical assessment and treatment of manic–depressive disorder in later life (e.g., Depp et al. 2004, Young et al. 2004, Sajatovic et al. 2005, Blow and Sajatovic 2007).

Older individuals with manic–depressive disorders can be considered of two types: those with later age of onset (usually at 40 or 50 years of age or older), and those with more typical younger onset. Evidence indicates that the former probably represent a subpopulation enriched with identifiable medical factors that may be the cause of mania, in particular neurological disorders, identified in 12–38%; however, the degree to which such factors are pathogenic is not clear (Depp et al. 2004), and there are insufficient grounds for considering late-onset manic–depressive disorder a separate subtype (Depp et al. 2004). Interestingly, manic–depressive disorder does not appear to worsen with age (Fenn et al. 2005), and the prevalence may decrease (Depp et al. 2004), though the extent to which each of these findings is due to selective mortality of the more severely ill at an earlier age is not clear.

Perhaps the key characteristic differentiating older from younger individuals, regardless of age of onset, is the increasing prevalence of medical comorbidity (Fenn et al. 2005); this study of inpatients indicated that those over 50 years of age had a median of 4 or more medical comorbidities requiring treatment, while another reported that 20% had 7 or more medical comorbidities (Brown 1998). Notably, while measures of physical quality of life decline with age, this trend is due to increasing prevalence of medical comorbidity, not age per se; thus attention to these comorbidities may improve quality of life (Fenn et al. 2005).

Unfortunately, no RCTs have yet been published specifically in older adults, and treatment is implemented based on data from all-age samples. Both early- and late-onset individuals of older age represent similar basic assessment and treatment issues, including the need to identify reversible causes and, especially in older individuals, the need to identify medical comorbidities and manage psychotropic medications accordingly. Several such management issues are highlighted in the following paragraphs.

As discussed in Chapters 101 and 123, tricyclic antidepressants may be associated with clinically significant cardiac conduction abnormalities, hypotension, sedation, glaucoma, and urinary retention particularly in the presence of prostatic hypertrophy. These are of even greater concern in the elderly. The risk of sedation due to neuroleptics and
Complications such as hip fracture (Ray et al. 1987) are not infrequently the initial event in a cascade of complications that can be terminal.

By contrast, lithium, carbamazepine, and valproic acid are relatively well tolerated in the elderly. However, careful attention must be given to three mechanisms of drug toxicity in this population: reduced renal clearance, multidrug protein-binding competition, and hepatic P-450 drug interactions. Second generation, and perhaps some first generation antipsychotics, have been associated with increased risk of cerebrovascular events, while agent-specific side effects ranging from sedation and hypertension to akathisia to metabolic syndrome must be considered (see Chapter 102).

The risk of clinically significant renal toxicity with appropriately dosed lithium is not great (Schou 1988, Gitlin 1993, Kheoe 1994). Although glomerular filtration rate decreases with age in persons treated with lithium, the rate of decline does not appear to be accelerated by lithium treatment (Lokkegaard et al. 1985, Vaamonde et al. 1986). Nonetheless, careful monitoring of renal function is needed in the elderly, especially those with additional risk factors for renal disease such as hypertension or diabetes. In addition, increasing age is a risk factor for hypothyroidism (Bauer et al. 1993), as is lithium use (Bauer et al. 1990). Thus, elderly persons taking lithium should be followed up carefully for decrements in thyroid function; however, hypothyroidism is not necessarily an indication for lithium discontinuation, as thyroid supplementation is straightforward. Treatment choice requires careful risk-benefit assessment in all patients, and in older individuals particularly, careful attention to the variety of increased medical risks that come with age is essential.

Clinical Vignette

Ms. B, a 59-year-old separated woman with type I disorder enrolled in a collaborative chronic care model (CCM; see Sections “Collaborative Chronic Care Models for Manic-Depressive Disorder” and “Issues in the Clinician-Patient Relationship”) after hospitalization for an acute manic episode with psychotic features. She was retired, separated, and had few social contacts. Although diagnosed with manic-depressive disorder 19 years earlier, she had had inconsistent mental health treatment. Episodes had been dramatic for her, often involving police bringing her to the hospital. Medical records documented that her denial of illness was the greatest barrier to treatment. Initially, she presented as distrustful and engaged in only limited discussion of her mood disorder. Gradually, psych-education group participation provided her with a sense of support and an ability to identify her own illness character-istics. She became proficient in identifying early warning symptoms of mood episodes and the benefits of consisten-cy in taking medications. She utilized personal cost-benefit analysis (Bauer and McBride 2003) to address medication side effects, and utilized easy access CCM appointments to remain in treatment rather than stopping medications as she had in the past. Although she had two more hospitalizations over the next 3 years, her daughter reported to the CCM staff, saying: “This program is the best thing that has happened to her...she has been so much better.”

Diagnostic Criteria for PMDD

Definition and Diagnostic Features

Premenstrual syndrome (PMS) is a combination of emotional, behavioral, and physical symptoms that occur in the premenstrual or luteal phase of the menstrual cycle. The term “premenstrual tension” appeared in the medical literature 70 years ago (Frank 1931), but widely accepted diagnostic criteria for PMS do not exist. Diagnostic criteria for PMS often require a minimum of one premenstrual symptom, such as the criteria proposed in the American College of Obstetrics and Gynecology Practice Guidelines (American College of Obstetrics and Gynecology 2000) or in the International Classification of Diseases, 10th Revision (World Health Organization 1993). Approximately 80% of women report at least mild premenstrual symptoms, 20–50% report moderate to severe premenstrual symptoms, and approximately 5% of women report severe symptoms for several days with impairment of role and social functioning (American Psychiatric Association 2000). The PMDD criteria require that role functioning be impaired as a result of the premenstrual symptoms. The functional impairment reported by women with PMDD is similar in severity to the impairment reported in major depressive disorder (MDD) and dysthymic disorder (Pearlstein et al. 2000, Halbreich et al. 2003). Women with severe PMS and PMDD have reported disruption in their social relationships, parenting roles, and work productivity as well as increased health-care utilization (Pearlstein et al. 2000, Chawla et al. 2002, Borenstein et al. 2003, Halbreich et al. 2003, Borenstein et al. 2005).

The PMDD criteria require that a woman prospectively rate her emotional, behavioral, and physical symptoms over two menstrual cycles to confirm the diagnosis. Several studies have reported that retrospective reports of premenstrual symptoms may inaccurately identify the timing or amplify the severity of symptoms compared to prospective reporting (Schnurr et al. 1994). Charting two menstrual cycles is advantageous, since some women have variability of symptom severity from cycle to cycle due to factors such as seasonal worsening, or a woman might have the unusual presence of follicular phase psychological symptoms due to a transient stressor. Studies conducted over the past two decades have used different instruments for daily ratings and various scoring methods to measure the premenstrual increase of symptoms (Schnurr et al. 1994). Recent studies utilize visual analog scales (Steiner et al. 1999) and Likert scale daily rating forms such as the Daily Record of Severity of Problems (Endicott et al. 2006) or Penn Daily Symptom Report (Freeman et al. 1996), with a scoring method that compares the average of symptom scores during the premenstrual days to the average of symptom scores postmenses.

A woman presenting with PMS should ideally bring to her clinician two cycles of an established daily rating form, or alternatively ratings of her most problematic symptoms, rated with anchor points ranging from “not present” to “severe.” The clinician should review the daily ratings to
confirm that the symptoms are in fact confined largely to the premenstrual phase, with the relative absence of symptoms in the follicular phase, and the clinician should also assess premenstrual functional impairment (Figure 68–1). Ratings that demonstrate follicular symptoms with increased symptom severity in the premenstrual phase suggest “premenstrual exacerbation” of an underlying disorder rather than PMDD. The DSM-IV-TR PMDD criteria state that the premenstrual symptoms should not be an exacerbation of an underlying disorder, but that PMDD could be superimposed on another disorder, like panic disorder. No formal guidelines exist for how to apply this criterion clinically.

**DSM-IV-TR Criteria**

**Diagnostic Criteria for PMDD**

*Research Criteria for Premenstrual Dysphoric Disorder*

A. In most menstrual cycles during the past year, 5 (or more) of the following symptoms were present for most of the time during the last week of the luteal phase, began to remit within a few days after the onset of the follicular phase, and were absent in the week postmenses, with at least one of the symptoms being either (1), (2), (3), or (4):

1. Markedly depressed mood, feelings of hopelessness, or self-deprecating thoughts
2. Marked anxiety, tension, feelings of being “keyed up,” or “on edge”
3. Marked affective lability (e.g., feeling suddenly sad or tearful or increased sensitivity to rejection)
4. Persistent and marked anger or irritability or increased interpersonal conflicts
5. Decreased interest in usual activities (e.g., work, school, friends, hobbies)
6. Subjective sense of difficulty in concentrating
7. Lethargy, easy fatigability, or marked lack of energy
8. Marked change in appetite, overeating, or specific food cravings
9. Hypersomnia or insomnia
10. A subjective sense of being overwhelmed or out of control
11. Other physical symptoms, such as breast tenderness or swelling, headaches, joint or muscle pain, a sensation of “bloating,” weight gain

B. The disturbance markedly interferes with work or school or with usual social activities and relationships (e.g., avoidance of social activities, decreased productivity and efficiency at work or school).

C. The disturbance is not merely an exacerbation of the symptoms of another disorder such as major depressive disorder, panic disorder, dysthymic disorder, or a personality disorder (although it may be superimposed on any of these disorders).

D. Criteria A, B, and C must be confirmed by prospective daily ratings during at least two consecutive symptomatic cycles. (The diagnosis may be made provisionally prior to this confirmation.)

**Differential Diagnosis**

Depression and anxiety disorders are the most common Axis I psychiatric disorders that may be concurrent and exacerbated premenstrually, with less clear evidence for bipolar disorder, post-traumatic stress disorder, eating disorders, and substance abuse (Endicott 1994, Hendrick et al. 1996, Pearlstein and Stone 1998, Kim et al. 2004). Since most PMDD symptoms are affective or anxiety related, “pure PMS” or PMDD is generally not diagnosed when an underlying depression or anxiety disorder is present; these women would be considered to have premenstrual exacerbation of their underlying depression or anxiety disorder. A recent study reported that 64% of the first 1500 women with MDD enrolled in the STAR*D study endorsed premenstrual exacerbation of their depressive symptoms by retrospective report (Kornstein et al. 2005). Another recent study reported that 68.5% of 1747 women with MDD and 65.1% of 665 women with bipolar I disorder retrospectively reported premenstrual mood symptoms (Payne et al. 2006). Personality disorders are not elevated in prevalence in women with PMDD (Critchlow et al. 2001), but women with PMDD and a personality disorder may demonstrate premenstrual phase amplification of personality dysfunction (Berlin et al. 2001). Schizophrenia may be an example of a disorder that does not have premenstrual exacerbation of psychotic symptoms but may have the superimposition of affective and anxiety symptoms of PMDD (Choi et al. 2001). The prevalence of premenstrually exacerbated disorders is unknown, and women with these conditions present frequently to their primary care clinician or gynecologist. The general guideline is to treat the underlying disorder first and see if subsequent daily ratings suggest persistence of premenstrual symptoms that might meet criteria for PMDD. Since most recent treatment studies have been conducted on women with PMS and PMDD without follicular symptomatology, this literature is not particularly informative on how to treat women with premenstrually exacerbated disorders.

Several medical conditions should also be considered when evaluating a woman with premenstrual complaints. Symptoms of endometriosis, polycystic ovary disease, thyroid disorders, adrenal system disorders, hyperprolactinemia, and panhypopituitarism may mimic symptoms of PMS. Several medical disorders may demonstrate a premenstrual increase in symptoms without accompanying emotional symptoms,
such as migraines, asthma, epilepsy, irritable bowel syndrome, diabetes, allergies, and autoimmune disorders (Pearlstein and Stone 1998, Case and Reid 2001). It is presumed that the menstrual cycle fluctuations of gonadal hormones influence some of the symptoms of these medical conditions.

**Course**

Premenstrual symptoms have been reported in women from menarche through perimenopause. Anecdotally many women report increasing severity of symptoms with advancing age and parity, but few longitudinal studies have been conducted evaluating the frequency and severity of premenstrual symptoms (Endicott et al. 1999). A 4-year longitudinal study of 1251 women 14–24 years of age in Munich, Germany, reported that both threshold and subthreshold PMS were relatively stable conditions (Wittchen et al. 2002). Mood lability, irritability, and anxiety have been reported to be the most stable premenstrual symptoms across cycles (Bloch et al. 1997). It has been hypothesized that women with PMDD are vulnerable to the development of affective disorders at other times of hormonal fluctuation across the reproductive years, such as the postpartum period and perimenopause. Retrospectively reported premenstrual symptoms have been identified as a predictor for perimenopausal depression in clinic and community samples (Richards et al. 2006). A study of perimenopausal women reported that prospectively rated premenstrual dysphoria and other premenstrual symptoms were significantly higher in women with perimenopausal depression compared to perimenopausal women without depression (Richards et al. 2006).

**Epidemiology**

The prevalence of PMDD has ranged from 4.6% to 6.4% in studies of women who prospectively rated their symptoms for at least one menstrual cycle (Rivera-Tovar and Frank 1990, Cohen et al. 2002b, Sternfeld et al. 2002). Approximately 20% of women have “subthreshold PMDD,” or severe PMS, due to having fewer and less severe symptoms or a lack of the functional impairment required to meet the PMDD criteria (Wittchen et al. 2002, Steiner et al. 2003). Studies with the prospective confirmation of diagnosis have not been conducted in adolescent girls younger than age 18 years, but studies with retrospective reports of premenstrual symptoms suggest possible higher prevalence rates of severe PMS in adolescents and association with symptoms of dysmenorrhea (Derman et al. 2004, Vichnin et al. 2006). Irritability has been identified as the most common premenstrual symptom in the United States and European samples (Endicott et al. 1999, Angst et al. 2001, Pearlstein et al. 2005c). A few studies have examined the prevalence of premenstrual symptoms with prospective ratings in non-United States or European countries. Prevalence rates of
severe PMS or PMDD have been reported to be 18.2% of 384 college students in Pakistan (Tabassum et al. 2005), 6.4% of 52 volunteer women in India (Banerjee et al. 2000), 12% of 150 women in a PMS clinic in Taiwan (Hsiao et al. 2002), and 2.4% of 83 women in a population cohort in Iceland (Sveindottir 1998). Some cultures and cultural subgroups describe more somatic than emotional symptoms (Hasin et al. 1998, van den Akker et al. 1995). Studies have failed to consistently identify predictors of PMDD such as age, parity, socioeconomic status, and menstrual cycle characteristics such as heavy bleeding or dysmenorrhea (Endicott et al. 1999, Steiner and Born 2000). Elevated lifetime prevalence of MDD in women with PMDD has been reported in several studies (Endicott 1994), as well as an elevated lifetime prevalence of postpartum depression (Critchlow et al. 2001).

Etiology and Pathophysiology

Genetic Factors
Studies of twin samples have suggested heritability of premenstrual symptoms (Condon 1993, Kendler et al. 1998, Trelloar et al. 2002). The overlap with genetic liability for PMS with MDD, seasonal affective disorder, and personality characteristics is unclear (Kendler et al. 1998, Praschak-Rieder et al. 2002, Trelloar et al. 2002). PMDD has been associated with multiple polymorphic alleles on the ERα gene (Rubinow and Schmidt 2006), but studies have failed to identify gene polymorphism differences between women with PMDD and controls on the serotonin transporter (Melke et al. 2003, Magnay et al. 2006), transcription factor activating protein-2 (Damberg et al. 2005), tryptophan hydroxylase, and monomine oxidase A promoter (Magnay et al. 2006) genes.

Neurobiological Factors
There are several reviews of pathophysiologic hypotheses of PMS and PMDD and their evidence (Parry 1997, Steiner and Pearlstein 2000, Backstrom et al. 2003, Halbreich 2003, Sundstrom-Poromaa et al. 2003). The majority of studies do not identify consistent abnormalities of hormones of the hypothalamic–pituitary–gonadal (HPG) axis, although a few studies have suggested altered luteinizing hormone (LH) pulse (Eriksson et al. 2006a). Data demonstrating consistent abnormalities of thyroid hormones, cortisol, prolactin, glucose, prostaglandins, beta-endorphins, vitamins, or electrolytes are lacking (Parry 1997, Halbreich 2003). Women with PMDD are more sensitive to the anxiolytic properties of carbon dioxide inhalation, lactate infusion, cholecystokinin tetrapeptide, and flumazenil, and increased adrenergic receptor binding may reflect abnormal noradrenergic function (Halbreich 2003). Women with PMDD have abnormal melatonin secretion and other circadian system abnormalities (Parry and Newton 2001).

Since consistent abnormalities in the HPG axis have not been identified, it is thought that premenstrual symptoms may occur due to a differential sensitivity to mood-perturbing effects of gonadal steroid fluctuations in women with PMS and PMDD (Schmidt et al. 1998). It is probable that the etiology of the “differential sensitivity” is multifactorial and in part genetically determined (Rubinow and Schmidt 2006). The specific neurotransmitter and neurosteroid abnormalities in women with PMS and PMDD are not known, but serotonin, norepinephrine, gamma-aminobutyric acid (GABA), allopregnanolone (ALLO), an anxiolytic metabolite of progesterone that acts at the GABA_A receptor), endorphins, and factors involved in calcium homeostasis may all possibly be involved. It has been proposed that women with PMDD have altered affective information processing and regulation during the luteal phase with abnormal activation patterns in specific brain regions (Rubinow and Schmidt 2006). Imaging studies have suggested altered serotonin function (Eriksson et al. 2006b, Jovanovic et al. 2006) and altered GABAergic function (Epperson et al. 2002, Smith et al. 2003) in women with PMDD compared to healthy controls.

A large number of studies have reported abnormalities in the serotonin system in women with PMS and PMDD. These include abnormal levels of whole blood serotonin, serotonin platelet uptake, and platelet tritiated imipramine binding; abnormal responses to serotonergic probes such as 1-tryptophan, buspirone, meta-chlorophenylpiperazine, and fenfluramine; and exacerbation of premenstrual symptoms after tryptophan depletion (Steiner and Pearlstein 2000, Parry 2001, Halbreich 2003). Several studies have also suggested that women with PMDD have decreased luteal phase levels of GABA, abnormal ALLO levels, and decreased luteal phase sensitivity of the GABA_A receptor as shown by flumazenil challenge, and the sedative and saccadic eye velocity responses to benzodiazepines and alcohol (Backstrom et al. 2003, Halbreich 2003, Sundstrom-Poromaa et al. 2003). It is possible that the rapid efficacy of selective serotonin reuptake inhibitors (SSRIs) in PMDD may be due in part to their ability to increase ALLO levels in the brain and enhance GABA_A receptor function (Eser et al. 2006). Alternative hypotheses for the fast action of SSRIs in PMDD include enhanced function of 5-HT_{2C} receptors (Landen and Thase 2006) and inhibition of the serotonin transporter with resulting decreased LH production (Clayton et al. 2006).

Several factors that influence calcium and bone homeostasis fluctuate with the menstrual cycle, and it is possible that some of these factors are abnormal in women with PMS and PMDD (Thys-Jacobs 2000). A recent case–control study reported that a high intake of calcium and vitamin D was associated with a lower risk of PMS by women's retrospective self-report (Bertone-Johnson et al. 2005). One study reported decreased bone mineral density in women with prospectively confirmed PMS (Thys-Jacobs et al. 1995); however, a later study in women with PMDD failed to find decreased bone mineral density compared to controls (Halbreich and Kahn 2001). It has been reported that women with PMS had reduced periovulatory calcium levels and elevated parathyroid hormone levels compared to controls, perhaps secondary to elevated preovulatory estrogen levels (Thys-Jacobs and Alvir 1995). It is possible that the administration of supplemental calcium normalizes the periovulatory fluctuations in calcium and parathyroid hormone, thus regulating calcium effects on neurotransmitter synthesis and release leading to affective symptom relief in women with PMS (Thys-Jacobs 2000).

Psychological and Social/Environmental Factors
Studies have suggested an association between stressful life events and daily stressors with PMS (Ross and Steiner...
2003). It has been proposed that PMS is specific to Western cultures due to family, society, and media influences that promote negative expectations and attitudes about the menstrual cycle (Anson 1999, Ross and Steiner 2003, Di Giulio and Reissing 2006). The attitude toward menstruation that develops with socialization is also influenced by cognitive processes. PMS has been reported to be more common in women who assign negative attributions to premenstrual symptoms, have poor coping strategies and problem-solving abilities, and feel that their symptoms are not in their control (Reading 1992, Di Giulio and Reissing 2006). In spite of possible altered cognitive processes in women with PMS or PMDD, cognitive performance is not abnormal in women with PMDD compared to controls (Resnick et al. 1998, Morgan and Rapkin 2002).

**Treatment**

**Treatment Goals**

Treatment strategies have largely followed the etiologic theories. The most systematically studied treatments have been the “correction” of neurotransmitter dysregulation with antidepressant or anxiolytic medications, or the elimination of hormonal fluctuations with ovulation suppression treatments. Different treatment modalities may differentially treat specific symptom profiles, but treatment studies have rarely reported efficacy for specific anxiety, mood, and behavioral and somatic symptom profiles (Halbreich et al. 2006).

**Somatic Treatments**

**Antidepressant Treatment**

The treatment studies of SSRIs in PMDD have suggested similar efficacy rates to treatment studies of SSRIs in MDD, with 60–70% of women responding to SSRIs compared to approximately 30% of women responding to placebo, depending on how response is defined (Halbreich et al. 2006). In general, the effective SSRI doses are similar to the doses recommended for the treatment of MDD (Figure 68–2). A systematic review of randomized controlled trials (RCTs) of SSRIs reported that women with severe PMS or PMDD were approximately seven times more likely to respond to SSRIs compared to placebo (Dimmock et al. 2000, Wyatt et al. 2002). This review included 12 trials with continuous (daily) dosing of fluoxetine, sertraline, paroxetine, citalopram, and fluvoxamine and four trials with intermittent dosing (SSRI administered during the luteal phase only from ovulation to menses) of sertraline and citalopram. The efficacy of continuous and intermittent dosing was equivalent based on the RCTs evaluated (Dimmock et al. 2000). Since this systematic review, one study of 167 women with severe PMS and PMDD reported that continuous and intermittent dosing of sertraline were equivalent in efficacy and both were superior to placebo (Freeman et al. 2004). However, another study has suggested that while both continuous and intermittent paroxetine were superior to placebo for irritability, affect lability, and mood swings, intermittent paroxetine was less

---

**Figure 68–2** Treatment algorithm of premenstrual symptoms.
effective than continuous paroxetine for depressed mood, low energy, food cravings, and somatic premenstrual symptoms in 167 women with PMDD (Landen et al. 2007). Thus, it remains a possibility that continuous SSRI dosing may be more effective than intermittent SSRI dosing for women with more severe and varied symptoms.

Two of the RCTs with continuous dosing included in the Dimmock and colleagues’ review involved samples of more than 200 women. One RCT compared fluoxetine 20 mg/day, 60 mg/day, and placebo over 6 months in 277 women with PMS (Steiner et al. 1995). Fluoxetine 20 mg/day was better tolerated than 60 mg/day, although both dosages were more efficacious than placebo in reducing premenstrual emotional, behavioral, and physical symptoms. Surprising results from this study included the fast onset of action of fluoxetine and the improvement of physical premenstrual symptoms (Steiner et al. 1995). The other large RCT involved daily flexible-dose sertraline over 3 months, and the average dose of 110 mg/day was more effective than placebo in reducing premenstrual symptoms (Yonkers et al. 1997) and improving psychosocial functioning in 243 women (Pearlstein et al. 2000). Since this review, two large RCTs have demonstrated superior efficacy of continuous dosing of paroxetine CR 12.5 and 25 mg/day compared to placebo over 3 months in reducing premenstrual mood and physical symptoms in 313 (Cohen et al. 2004) and 359 (Pearlstein et al. 2002b) women with PMDD. In both studies, the 25-mg daily dose of paroxetine CR was more effective than the 12.5-mg daily dose in the improvement of premenstrual functioning and the reduction of premenstrual physical symptoms.

Since the review of Dimmock and colleagues, RCTs have also further established the efficacy of intermittent dosing, or luteal phase dosing, from ovulation to menses of fluoxetine, sertraline, and paroxetine CR. Fluoxetine 20 mg/day during the luteal phase only was superior to placebo in reducing premenstrual emotional and physical symptoms in 252 women with PMDD, while fluoxetine 10 mg/day during the luteal phase only was superior to placebo in reducing emotional symptoms but not physical symptoms (Cohen et al. 2002a). Sertraline 50–100 mg/day during the luteal phase only was superior to placebo for improving premenstrual emotional symptoms and impaired functioning, but not premenstrual physical symptoms in 200 women with PMDD (Halbreich et al. 2002). Another RCT reported that luteal phase dosing of paroxetine CR 12.5 and 25 mg/day were superior to placebo in reducing premenstrual symptoms in 366 women with PMDD (Steiner et al. 2005). Studies involving intermittent dosing have reported the absence of discontinuation symptoms when fluoxetine, sertraline, and paroxetine CR at the given doses were abruptly stopped the first day of menses. Intermittent dosing continues to be effective for symptoms that continue into the first few days of menses even when the antidepressant is discontinued on the first day of menses (Yonkers et al. 2002b). The United States Food and Drug Administration (FDA) has approved the use of continuous and intermittent dosing of fluoxetine, sertraline, and paroxetine CR for women with PMDD with specific dosage recommendations (see Figure 68–2).

The efficacy of intermittent dosing, as well as the finding from most continuous dosing SSRI trials that efficacy is achieved by the first treatment cycle, has suggested a more rapid and different mechanism of action of SSRIs in PMDD compared to its effects in MDD, which typically takes 3–6 weeks. As mentioned above, one hypothesis explaining the rapid improvement of premenstrual symptoms by SSRIs may be an increase in ALLO. This hypothesis suggests that it may not be necessary to begin the SSRI by ovulation. Some studies have evaluated the efficacy of SSRIs for “symptom onset” dosing of SSRIs, i.e., administering SSRIs from the postovulatory day that premenstrual symptoms appear until menses. Interestingly, weekly fluoxetine 90 mg administered just 1 week prior to the expected onset of menses was not superior to placebo, but fluoxetine 90 mg administered 2 weeks and 1 week prior to the expected onset of menses in 257 women with PMDD was reported to be superior to placebo in reducing premenstrual emotional symptoms and improving premenstrual functioning, but not premenstrual physical symptoms (Miner et al. 2002). Symptom-onset dosing of low-dose sertraline (25–50 mg/day) was reported to be superior to placebo in reducing premenstrual symptoms in 296 women with prospectively confirmed PMS (Kornstein et al. 2006). Preliminary studies in women with PMDD have suggested superiority of symptom-onset paroxetine compared to placebo (Yonkers et al. 2006) and efficacy with both symptom-onset and luteal phase escitalopram dosing, although luteal phase dosing was more effective for women with severe symptoms (Freeman et al. 2005).

Daily dosing of immediate release venlafaxine, an antidepressant with both serotonergic and noradrenergic action, was reported to be superior to placebo in the reduction of emotional and physical symptoms of PMDD in 157 women (Freeman et al. 2001b). Smaller RCTs have reported efficacy with clomipramine, a tricyclic antidepressant with largely serotonergic action, in daily dosing (Sundblad et al. 1992) and luteal phase dosing (Sundblad et al. 1993). The doses of clomipramine reported to be effective for PMS (25–75 mg/day) are lower than expected effective doses for MDD (see Figure 68–2). One RCT reported that nefazodone was not superior to placebo in PMS (Landen et al. 2001); however, increasing nefazodone in the luteal phase was reported to improve premenstrual exacerbation of MDD in a small crossover study (Miller et al. 2002). Three RCTs have compared SSRIs to nonserotonergic antidepressants and placebo, and each has reported specific efficacy of the SSRI over placebo and the nonserotonergic antidepressant. A large study compared sertraline to desipramine and placebo (Freeman et al. 1999), and two smaller studies compared paroxetine to maprotiline and placebo (Eriksson et al. 1995), and fluoxetine to bupropion and placebo (Pearlstein et al. 1997). The differential superiority of serotonergic antidepressants compared to noradrenergic antidepressants is compatible with the proposed serotonin dysfunction in PMDD.

Most SSRI trials have been 3 months or less in duration, and although a few open studies suggest maintenance of SSRI efficacy over 1–2 years, evidence-based long-term treatment recommendations do not exist. Clinically, many women note the recurrence of premenstrual symptoms after SSRI discontinuation and many women choose to take SSRIs over a long period of time. Studies are needed to identify whether or not some women develop tolerance to the SSRI and need a higher dose over time and whether or not some women stay in remission for a period of time.
following SSRI discontinuation. Future studies also need to systematically compare the efficacy and predictors of response to symptom-onset, luteal phase, and continuous daily SSRI dosing in women with PMDD. In addition, systematic studies are needed of the “bumping up,” or semi-intermittent dosing, of SSRIs in women with premenstrual exacerbation of an underlying depressive or anxiety disorder. In these women, SSRI dose is increased during the luteal phase and decreased back to the usual dose at menses (Steiner et al. 2006).

**Oral Contraceptives**

Even though oral contraceptives (OCs) have been commonly prescribed by gynecologic and medical clinicians for the treatment of PMS, until recently there was minimal literature endorsing their efficacy. Surveys of population cohorts without defined PMS or PMDD have reported that OCs do not alter mood in most women, but a subset of women reports improvement of premenstrual symptoms, and another subset reports the production of adverse premenstrual symptoms (Sanders et al. 2001, Joffe et al. 2003). Two older RCTs in samples with confirmed PMS reported a lack of efficacy with monophasic or triphasic OCs (Backstrom et al. 1992, Graham and Sherwin 1992). A more recent RCT compared an OC containing ethinyl estradiol 30 μg and drospirenone 3 mg to placebo in 82 women with PMDD (Freeman et al. 2001a). Both the OC and placebo improved most premenstrual symptoms, and the OC was significantly more efficacious than placebo only in decreasing food cravings, increased appetite, and acne. However, an OC containing ethinyl estradiol 20 μg and drospirenone 3 mg, Yaz®, administered as 24 days of active pills followed by a 4-day hormone-free interval, has been reported to be superior to placebo in reducing premenstrual emotional and physical symptoms in a 3-month parallel study in 450 women with PMDD (Yonkers et al. 2005a) and in a crossover design study in 64 women with PMDD (Pearlstein et al. 2005a). In addition to the improvement noted on the daily symptom self-ratings, clinician ratings of PMDD demonstrated improvement, and self-ratings of quality of life improved with Yaz® compared to placebo. The efficacy of this particular OC may be due to its administration in a 24/4 regimen, which provides more stable hormone levels and reduces adverse symptoms that can occur during withdrawal bleeding, and may also be due to the unique antimineralocorticoid and anti-androgenic properties of drospirenone (Pearlstein et al. 2005a, Yonkers et al. 2005a). In 2006, Yaz® received FDA approval for the treatment of PMDD in women desiring oral contraception.

**Other Ovulation Suppression Treatments**

Gonadotropin-releasing hormone (GnRH) agonists suppress ovulation by downregulating GnRH receptors in the hypothalamus, leading to decreased follicle-stimulating hormone (FSH) and LH release from the pituitary, resulting in decreased estrogen and progesterone levels. GnRH agonists are administered parenterally (e.g., subcutaneous monthly injections of goserelin, intramuscular monthly injections of leuprolide, and daily intranasal buserelin) (see Figure 68–2). Ten double-blind, placebo-controlled studies of GnRH agonists in PMS and PMDD have been published to date, and GnRH agonists are reported to be superior to placebo in eight of these studies (Backstrom et al. 2003, Pearlstein 2004). A meta-analysis of five of these published studies suggested an odds ratio of 8.66 that GnRH agonists will lead to improvement in premenstrual emotional and physical symptoms compared to placebo (Wyatt et al. 2004). After relief of PMS is achieved with a GnRH agonist, “add-back” hormone strategies have been investigated due to the undesirable medical consequences of the hypoestrogenic state resulting from prolonged anovulation. Although the “add-back” of estrogen and progesterone to goserelin (Leather et al. 1999) and leuprolide (Schmidt et al. 1998) has been reported to cause the reappearance of mood and anxiety symptoms, the meta-analysis concluded that “add-back” hormones did not reduce the efficacy of GnRH agonists (Wyatt et al. 2004). Since women with severe PMS and PMDD have an abnormal response to normal hormonal fluctuations (Schmidt et al. 1998), it is not surprising that some women may have the induction of mood and anxiety symptoms from the addition of gonadal steroids, reducing the benefit of the replacement strategy. Other suggested replacement strategies have included low-dose pulsed progesterone (Mitwally et al. 2002) and tibolone, a synthetic steroid with estrogenic, androgenic, and progestogenic properties (Di Carlo et al. 2001). More research is needed to evaluate the safety of long-term use of GnRH agonists and replacement hormonal treatments.

Danazol, a synthetic steroid, alleviates premenstrual symptoms when administered at 200–400 mg q.d. doses that induce anovulation (Hahn et al. 1995). A study with danazol 200 mg/day administered during the luteal phase only, not causing anovulation, reported that breast tenderness but not other premenstrual symptoms were reduced (O’Brien and Abukhalil 1999). Anovulation due to the administration of estrogen or progesterone throughout the cycle or from oophorectomy is not common treatment, largely due to the medical risks from the prolonged anovulatory state, leading to the same long-term health issues as with GnRH agonists. The small literature with estrogen or progesterone administered most of the cycle has yielded mixed reports (Epperson et al. 1999, Backstrom et al. 2003). Two small studies reported relief of intractable PMS with hysterectomy and bilateral oophorectomy (Casper and Hearn 1990, Casson et al. 1990). Hysterectomy with oophorectomy is considered a last-resort treatment option for women with severe PMDD who do not respond to more conventional treatments (Cronje et al. 2004, Studt 2006).

**Progesterone**

The early assumption that PMS was due to a progesterone deficiency, which has never been substantiated, led to luteal phase progesterone being one of the earliest treatments of PMS in the literature. A systematic review of published double-blind, placebo-controlled randomized studies of luteal phase progesterone (given as vaginal suppositories or oral micronized tablets) and progestogens reported that there was no clinically meaningful difference between all progesterone forms and placebo, although there was a small statistically significant superiority of progesterone over placebo (Wyatt et al. 2001). There was a slight advantage for oral micronized progesterone, and the authors postulated that this may be due to the increase in ALLO levels derived from this form of progesterone. A more recent systematic
review concluded that due to the methodological shortcomings of previous studies, it is not possible to establish whether or not progesterone is helpful for PMS or PMDD (Ford et al. 2006).

Other Medications
Alprazolam (administered during the luteal phase) has been reported to be superior to placebo in most studies (Smith et al. 1987, Harrison et al. 1990, Berger and Presser 1994, Freeman et al. 1995) but not all (Schmidt et al. 1993), and although it has a lower efficacy rate than SSRIs, it is effective for premenstrual emotional symptoms. Alprazolam should be tapered over the first few days of menses each cycle. An early (Rickels et al. 1989) and a more recent (Landen et al. 2001) study of buspirone 25 mg/day during the luteal weeks indicated some efficacy. Spironolactone has been reported to decrease premenstrual emotional and physical symptoms (Wang et al. 1995). Bromocriptine has been reported to decrease premenstrual breast tenderness (Andersch 1983). Previous studies reporting efficacy that deserve further study include nonsteroidal anti-inflammatory drugs (Mira et al. 1986), doxycycline (Toth et al. 1988), naltrexone (Chuang et al. 1988), and atenolol (Rausch et al. 1988).

Herbal and Complementary Treatments
Evidence-based reviews of complementary treatments have reported that the strongest evidence exists for benefit with chasteberry, or vitex agnus castus (Stevinson and Ernst 2001, Domoney et al. 2003, Fugh-Berman and Kronenberg 2003, Girman et al. 2003, Denney 2006). In addition to the studies cited in these reviews, chasteberry has been reported to reduce premenstrual symptoms in an open study of 118 women with PMDD (Prilepskaya et al. 2004). Chasteberry and fluoxetine were compared in an RCT involving 41 women with PMDD, and although both treatments were effective, fluoxetine was better for emotional symptoms and chasteberry was better for physical symptoms (Atmaca et al. 2003). It is hypothesized that the benefit of chasteberry for premenstrual symptoms could be due to its being a dopamine agonist with possible reductions of FSH or prolactin levels (Girman et al. 2003). The evidence-based reviews concluded that RCTs have not suggested consistent benefit for ginkgo biloba, evening primrose oil, and homeopathic treatments but that initial positive RCTs suggest further study of massage, reflexology, biofeedback, and chiropractic manipulation. Qi therapy (an oriental complementary mind–body therapy involving energy flows) was reported to be superior to placebo in 36 women with prospectively confirmed PMS (Jang and Lee 2004). There have been positive open reports, but no RCTs, with acupuncture, yoga, guided imagery, photic stimulation, and hypericum (Pearlstein 2004).

Dietary Supplementation
A large RCT compared calcium 600 mg h.i.d. and placebo in 466 women with PMDD (Thys-Jacobs et al. 1998). Calcium was reported to have a 48% efficacy rate for reducing the emotional and physical symptoms of the PMDD diagnostic criteria, except for fatigue and insomnia, compared to 30% for placebo. However, women with concurrent psychiatric illness were not clearly excluded, and other treatments except for analgesics were allowed. The efficacy of calcium was somewhat less in women who were also taking OCs. The results of this study were notable, and calcium deserves further study.

Several early studies were conducted with vitamin B₆ for the treatment of PMS, and a review of the early studies reported a lack of efficacy (Kleijnen et al. 1990). A meta-analysis of nine controlled trials including 940 women with PMS indicated only weak support for vitamin B₆ (50–100 mg/day) in reducing premenstrual symptoms (Wyatt et al. 1999). Two small RCTs have suggested efficacy with magnesium (Facchinetti et al. 1991, Walker et al. 1998), but other studies have failed to document magnesium deficiency in women with PMDD or superior efficacy of supplemental magnesium in reducing premenstrual mood symptoms compared to placebo (Khine et al. 2006). An RCT reported superior efficacy with tryptophan compared to placebo in women with PMDD (Steinberg et al. 1999) and an early study that suggested efficacy for vitamin E deserves replication (London et al. 1987). An initial study evaluating the effect of fish oil on premenstrual symptoms suggested promise (Sampalis et al. 2003). Several trials have been conducted with multinutrients containing several vitamin and mineral components. As reviewed, results from these studies have been mixed and several of the supplements studied contained quantities of vitamins that exceeded daily recommended levels (Bendich 2000, Stevinson and Ernst 2001).

Lifestyle Modifications and Psychosocial Treatments
Many lifestyle modifications and psychosocial treatments have been suggested for PMS. Lifestyle modifications are often suggested through self-help materials or in an individual or group psychoeducation format. One study reported that a weekly peer support and professional guidance group for four sessions was superior to waitlist control in terms of reducing premenstrual symptoms. The treatment consisted of diet and exercise regimens, self-monitoring and other cognitive techniques, and environment modification (Taylor 1999). Another study reported that a four-session group intervention over 18 weeks emphasizing diet, exercise, and a positive reframing of a woman’s perceptions of her menstrual cycle experiences was superior to a control condition for reducing premenstrual symptoms (Morse 1999). Few studies have been conducted on individual lifestyle or psychosocial treatments to identify which components are most efficacious.

Dietary recommendations include decreased caffeine, frequent snacks or meals, reduction of refined sugar and artificial sweeteners, and increase in complex carbohydrates. Reduction of salt, foods with high saturated fat, and red meat has also been suggested. It is hypothesized that the maintenance of a steady serum glucose level through the ingestion of complex carbohydrates may decrease premenstrual food cravings and increase the availability of tryptophan in the brain for serotonin synthesis (Pearlstein 2004). To date, only two RCTs have examined a specific dietary regimen. Both RCTs compared a beverage containing simple and complex carbohydrates to an isocaloric placebo beverage that did not increase tryptophan availability. Both studies reported that the beverage containing simple
and complex carbohydrates was superior for reducing premenstrual dysphoria and other symptoms (Sayegh et al. 1995, Freeman et al. 2002).

Exercise is a frequently recommended treatment for PMS that has yet to be tested in a sample of women with prospectively confirmed PMS or PMDD. As reviewed, negative affect and other premenstrual symptoms improve with regular exercise in women in general (Pearlstein 1996, Scully et al. 1998). It is not clear if aerobic exercise is superior to nonaerobic exercise in terms of symptom relief. Relaxation has likewise had little systematic study in PMS; one RCT reported that relaxation therapy was superior to both symptom charting and leisure reading (Goodale et al. 1990). Cognitive therapy (CT) is consistently reported to be an effective treatment for women with PMS. Two studies in women with prospectively confirmed PMS reported superiority of individual CT over a waitlist control (Blake et al. 1998) and superiority of group CT over information-focused therapy (Christensen and Oei 1995) for reducing premenstrual symptoms. A more recent RCT examined the relative efficacy of fluoxetine 20 mg/day, 10 individual CT sessions, or their combination, in women with PMDD (Hunter et al. 2002a, 2002b). Efficacy rates at 6 months were comparable between the three treatments; however, at 1 year, women who had received CT were coping better than those who had received fluoxetine alone.

Other Treatments

Although a crossover study reported that evening bright light for two premenstrual weeks decreased depression and tension (Lam et al. 1999), a meta-analysis of the few existent trials suggested a small effect size for bright light therapy (Krasnik et al. 2005). As reviewed, both light therapy and sleep deprivation may decrease premenstrual dysphoria by correcting abnormal circadian rhythms found in women with PMDD (Parry and Newton 2001).

Special Factors Influencing Treatment

One of the unique aspects of treating women with severe PMS and PMDD is that symptoms, although cyclical, may be present for 40 years of a woman’s life. Even though evidence-based long-term studies of efficacy and adverse effects are lacking, many women receive pharmacotherapy for PMDD for many years. One issue that arises with long-term antidepressant use is planned or inadvertent conception. Women and their partners need to have the risks of fetal exposure to the SSRIs, anxiolytics, and other pharmacologic treatments be part of the informed consent process. Some women with PMDD will discontinue medications prior to trying to conceive, other women will choose to stay on the medication with discontinuation once pregnancy occurs. Pharmacotherapy is often started postpartum when menses resume, and the risks of psychotropic medications with breastfeeding need to be considered. Adverse effects are another issue that arises with long-term pharmacotherapy treatment for PMDD. Although many women are satisfied with the improvement of their premenstrual emotional and physical symptoms with SSRI use, they may have accompanying weight gain, decreased libido and delayed orgasm. Women may try different SSRIs and different dosing regimens in search of the long-term treatment option with the fewest adverse effects, but many women continue to have long-term adverse effects.

Conclusion

Women with severe PMS and PMDD comprise a substantial proportion of menstruating women. These women have several symptomatic days each month that lead to disrupted relationships and decreased quality of life. Women presenting with premenstrual complaints should prospectively rate their symptoms for two menstrual cycles to rule out the presence of a concurrent psychiatric or medical disorder. Once the diagnosis of severe PMS or PMDD is confirmed, SSRI medication is considered the first-line treatment (American College of Obstetrics and Gynecology 2000, Altshuler et al. 2001, Steiner et al. 2006). SSRIs medication may be effective when administered daily or intermittently (from ovulation to menses). Nutritional approaches, exercise, calcium, chasteberry, and CT may be appropriate as first treatments in mild cases, otherwise they may accompany medication treatment (Altshuler et al. 2001). Prior to the FDA approval of the first OC for PMDD, second-line treatment options included changing to a second SSRI, hormone therapy (such as GnRH agonists), or adding adjunctive anxiolytics or other medications targeted to specific symptoms (American College of Obstetrics and Gynecology 2000, Altshuler et al. 2001). Now the OC, Yaz®, containing 20 μg of ethinyl estradiol and 3 mg of drospirenone, could be considered an alternative first-line treatment in women with PMDD desiring contraception. Future studies are still needed for women with severe PMS and PMDD, such as to identify predictors for which women may benefit from SSRIs versus hormonal strategies, to examine the possible benefit of SSRIs and a hormonal treatment, and to determine the optimal duration for medication treatment.

Clinical Vignette

Ms. A is a 34-year-old married woman who presents to her gynecologist for her first annual examination since giving birth to her third child 6 months before. Ms. A had always noted 2–3 days of irritability, mood swings, and cravings for chocolate before her menses prior to conceiving her third child, but she did not feel that these symptoms had interfered with her functioning. Since her menses has resumed in the past year, Ms. A has noted 10–14 days of tension, lack of patience, yelling at her husband and children, feeling more sensitive and overwhelmed, low energy, feeling more clumsy, increased appetite and cravings for sweets, desire to be alone, abdominal bloating, and breast tenderness. Ms. A tells her gynecologist that now the symptoms are interfering with her quality of life and her functioning as a homemaker and she requests medication for her symptoms. Ms. A has an unremarkable psychiatric or medical history.

Ms. A is given a self-help pamphlet that details the recommended dietary, exercise, and lifestyle modifications. She is also encouraged to chart her most troublesome symptoms daily. The gynecologist discusses pharmacological treatment options that Ms. A should consider once the daily charting is reviewed and the diagnosis of PMS or PMDD is confirmed, including SSRIs, an OC, and dietary supplements.

Introduction
Descriptions of cases resembling agoraphobia date back thousands of years, appearing in the writings of Hippocrates and others. The term agoraphobia was, however, coined less than 150 years ago by Westphal (1871) to describe patients who appeared to be experiencing panic attacks accompanied by anticipatory anxiety and functional incapacitation when walking the streets of their neighborhoods. Westphal wrote that “it is not possible for them to walk across open spaces and through certain streets... they are troubled in their freedom and movement... they absolutely do not know the reasons for this fear... it comes by itself; a sudden occurrence, strange thing... [and] stimulation of alcohol makes it easier to overcome” (translated by Knapp and Schumacher 1988). Although this description alludes to a panic-like occurrence, Westphal did not make an association between panic attacks and agoraphobia. Freud (1894/1949), whose description of anxiety attacks holds many similarities (but also some notable differences) to contemporary descriptions of panic disorder, was the first to explicate this association. In describing agoraphobia, he specifically mentioned the role of panic, anticipatory anxiety, and escape concerns as central to the condition (Freud 1895/1949). Interestingly, the writings of

Clinical Vignette 1
Sandra B. was a 20-year-old college student who presented to a student health clinic reporting recurrent panic attacks. Her first attack occurred seven months earlier while smoking marijuana at an end-of-term party. At the time she felt depersonalized, dizzy, short of breath, and her heart was beating wildly. Sandra had an overwhelming fear that she was going crazy. Friends took her to a nearby hospital emergency department where she was given a brief medical evaluation, reassured that she was simply experiencing anxiety, and given a prescription for lorazepam. In the following months, Sandra continued to experience unexpected panic attacks and became increasingly convinced that she was losing control of her mind. Most of her panics occurred unexpectedly during the day, although they sometimes also occurred at night, violently wrenching her from a deep, dreamless sleep. Sandra began avoiding a variety of substances (e.g., alcohol, marijuana, coffee) and activities (e.g., aerobics classes) because they produced bodily sensations, such as palpitations and dizziness, which she feared. She believed that if these sensations became too intense then she might “tip over the edge” into insanity. Increasingly, Sandra also began to avoid shopping malls, lecture halls, and other public places for fear that she would have a panic attack and lose control. Whenever she contemplated entering these situations, she became highly anxious and sometimes panicked if she actually entered them. As a result of avoiding lectures, her grades began to fall and she was at risk for failing her courses. She became increasingly depressed and, at times, contemplated suicide as a way of ending her misery. At the urging of a roommate, she eventually sought help from the student health clinic.
both Westphal and Freud allude to mechanisms and processes that today comprise part of modern psychological and biological models of panic disorder. These models are discussed in detail in the sections that follow below.

Reference to panic-like symptoms can also be found in the writings about popular historical figures such as Darwin and in the cardiology literature. Some of the terms used in this literature began to appear in conjunction with DaCosta’s work on American Civil War soldiers (e.g., irritable heart, DaCosta’s syndrome, soldiers heart) and subsequent observations of those participating in World Wars I and II (e.g., effort syndrome, neurocirculatory asthenia, cardiac neurasthenia). The early cardiology literature is replete with attempts to link panic-like symptoms to some form of cardiac pathology, most notably mitral valve prolapse. Research has for the most part failed to support this hypothesis (Sivaramakrishnan et al. 1994).

The origin of the panic disorder construct as a separate diagnostic entity was influenced by the work of a number of researchers but none so much as Donald Klein in the late 1950s and early 1960s (Klein 1980). Klein observed that, contrary to expectation, a subgroup of patients with anxiety neurosis did not improve on chlorpromazine (an antipsychotic sedative) and in some cases became worse. When he gave this subgroup imipramine, a compound newly introduced in the 1950s, which was derived from modifications to chlorpromazine, marked improvements were observed. Prior to taking imipramine these patients, unlike those who were responsive to chlorpromazine, had been experiencing rapid rushes of terror, racing hearts, and other physical sensations, which prompted them to rush to the nurses station with reports that they were about to die. On the basis of this differential drug response, Klein concluded that imipramine was effective against these seemingly spontaneous episodes of panic and, importantly, that these attacks were distinct from other forms of anxiety. He also suggested that agoraphobia was a consequence of spontaneous panic attacks.

Due in large part to the pioneering work of Klein and his colleagues, anxiety neurosis was later divided in the Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) (American Psychiatric Association 1980) into generalized anxiety disorder and panic disorder. Diagnosis of panic disorder required a minimum of three panic attacks that were of sudden onset, involved at least 4 of 12 symptoms, and occurred within a three-week period. Phobic neurosis was divided into simple phobia, social phobia, and agoraphobia. Agoraphobia without panic attacks was considered to be conceptually distinct from agoraphobia with panic attacks.

The distinction between agoraphobia with and without panic was dropped in the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) (American Psychiatric Association 1987). Despite evidence that it is rare (Grant et al. 2006, Kessler et al. 2006), agoraphobia without a history of panic disorder remained a separate codable diagnosis. The DSM-III-R was restructured to include separate diagnoses for panic disorder without agoraphobia and panic disorder with agoraphobia. Diagnosis of panic disorder required (1) at least 4 panic attacks (of sudden onset and comprising at least four of 13 symptoms) in a four-week period or (2) one or more unexpected attacks followed by at least one month of persistent worry over subsequent attacks. Changes in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) (American Psychiatric Association 1994) and Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000), as described in detail below, involved removal of the criteria sets for panic attacks and agoraphobia from the criteria set for panic disorder and refinements to the definition of panic disorder necessitating both recurrent unexpected attacks and associated persistent worry or behavioral change.

Diagnosis

Definition and Diagnostic Features

DSM-IV-TR Definition and Diagnostic Criteria

According to DSM-IV-TR, panic disorder is defined by recurrent and unexpected panic attacks. At least one of these attacks must be followed by one month or more of

1. persistent concern about having more attacks,
2. worry about the implications or consequences of the attack, or
3. changes to typical behavioral patterns (e.g., avoidance of work or school activities) as a result of the attack.

In addition, the panic attacks must not stem solely from the direct effects of illicit substance use, medication, or a general medical condition (e.g., hyperthyroidism, vestibular dysfunction) and are not better explained by another mental disorder (e.g., social phobia for attacks that occur only in social situations). A diagnosis of panic disorder with agoraphobia is warranted when the criteria for panic disorder are satisfied and accompanied by agoraphobia (i.e., anxiety about being in a place or a situation that is not easily escaped or where help is not easily accessible if panic occurs).

Although panic attacks are a cardinal feature of panic disorder and, in combination with agoraphobia, are essential to a diagnosis of panic disorder with agoraphobia, the criteria sets for panic attacks and for agoraphobia are listed separately as standalone noncodable conditions that are referred to by the diagnostic criteria for panic disorder and agoraphobia without history of panic disorder. Notwithstanding, accurate diagnosis is difficult without a sufficient understanding of these features. Tables 69–1 and 69–2 show the DSM-IV-TR criteria for panic attack and agoraphobia, respectively. While the criteria for agoraphobia are generally straightforward, panic attacks can be difficult to understand.

Several studies have shown that people report having what they consider to be a panic attack during or in association with actual physical threat (i.e., a true alarm situation; Barlow 2004). It is, however, important to distinguish between a fear reaction in response to actual threat and a panic attack. In an attempt to do so, the DSM-IV-TR has clarified that panic attacks occur “in the absence of real danger” (Barlow 2004, p 430). Such attacks involve a paroxysmal occurrence of intense fear or discomfort accompanied by a minimum of 4 of the 13 symptoms shown in Table 69–1. The DSM-IV-TR recognizes three characteristic types of panic attacks, including those that are unexpected (i.e., not associated with an identifiable internal or external trigger and appear to occur “out of
Definition and Criteria for Panic Attack

A panic attack is a discrete period of intense fear or discomfort in the absence of real danger that develops abruptly, reaches a peak within 10 min, and is accompanied by four (or more) of the following symptoms:

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, light-headed, or faint
9. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
10. Fear of losing control or going crazy
11. Fear of dying
12. Paresthesias (numbness or tingling sensations)
13. Chills or hot flushes

The panic attack must peak within 10 min, and is accompanied by at least four of these symptoms.

DSM-IV-TR Criteria

Panic Disorder with Agoraphobia
A. Both (1) and (2):
(1) recurrent unexpected panic attacks
(2) at least one of the attacks has been followed by one month (or more) of one (or more) of the following:
(a) persistent concern about having additional attacks
(b) worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, going crazy)

B. The presence of agoraphobia.

C. The panic attacks are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).

D. The panic attacks are not better accounted for by another mental disorder, such as social phobia (e.g., occurring on exposure to feared social situations), specific phobia (e.g., on exposure to a specific phobic situation), obsessive–compulsive disorder (e.g., on exposure to dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., in response to stimuli associated with a severe stressor), or separation anxiety disorder (e.g., in response to being away from home or close relatives).

Panic Disorder without Agoraphobia
A. Both (1) and (2):
(1) recurrent unexpected panic attacks

Table 69-1 | Definition and Criteria for Panic Attack

Table 69-2 | Criteria for Agoraphobia

The term limited symptom attacks is used to refer to panic-like episodes comprising fewer than four symptoms.

Although unexpected panic attacks are required for a diagnosis of panic disorder, not all panic attacks that occur in panic disorder are unexpected. The occurrence of unexpected attacks can wax and wane and over the developmental course of the disorder they tend to become situationally bound or predisposed. Moreover, unexpected panic attacks as well as those that are situationally bound or predisposed can occur in the context of other psychiatric disorders, including all of the other anxiety disorders (e.g., a person with social phobia might have an occasional unexpected panic attack without the other features required to diagnose panic disorder; a dog phobic might panic whenever a large dog is encountered) (Barlow 2004) and some general medical conditions. A clear understanding of the distinction between types of panic attacks outlined in the DSM-IV-TR provides a foundation for diagnosis and differential diagnosis (discussed below). As described by Taylor (2000), however, consideration of other characteristics of panic—including duration of attacks, frequency of attacks, number and intensity of symptoms, nature of catastrophic thinking, and mechanism responsible for termination of an attack—can be important in identifying exacerbating and controlling factors.
(2) at least one of the attacks has been followed by 1
month (or more) of one (or more) of the follow-
ing:
(a) persistent concern about having additional
attacks
(b) worry about the implications of the attack or
its consequences (e.g., losing control, having a
heart attack, going crazy)
B. Absence of agoraphobia.
C. The panic attacks are not due to the direct
physiological effects of a substance (e.g., a drug
of abuse, a medication) or a general medical
condition (e.g., hyperthyroidism).
D. The panic attacks are not better accounted for by
another mental disorder, such as social phobia
(e.g., occurring on exposure to feared social
situations), specific phobia (e.g., on exposure to a
specific phobic situation), obsessive-compulsive
disorder (e.g., on exposure to dirt in someone
with an obsession about contamination),
posttraumatic stress disorder (e.g., in response
to stimuli associated with a severe stressor), or
separation anxiety disorder (e.g., in response to
being away from home or close relatives).

**Assessment**

The most comprehensive and accurate diagnostic information
emerges when the clinician uses open ended questions and empathic listening, combined with structured inquiry about specific events and symptoms (American Psychiatric Association 1995). Useful structured interviews include the *Structured Clinical Interview for DSM-IV-TR* (SCID-IV) (First et al. 1996) and the *Anxiety Disorders Interview Schedule for DSM-IV-TR* (ADIS-IV; Di Nardo et al. 1994). A complete assessment for panic disorder also includes a general medical evaluation (American Psychiatric Association 1995), consisting of a medical history, review of organ systems, physical examination, and blood tests. A general medical evaluation is important for identifying general medical conditions that mimic or exacerbate panic attacks or panic-like symptoms (e.g., seizure disorders, cardiac conditions, pheochromocytoma). These disorders should be investigated and treated before contemplating a course of panic disorder treatment. It is also important to rule out the other anxiety disorders and major depressive disorder as primary factors in the person’s panic attacks and avoidance prior to initiating treatment for panic disorder. A decision tree for assessment and differential diagnosis of patients presenting with panic attacks is presented in Figure 69–1.

Diagnostic information can be usefully supplemented by short self-report questionnaires to assess the severity of symptoms and other variables (Taylor 2000). The *Beck Depression Inventory* (Beck and Steer 1987) and *Beck Anxiety Inventory* (Beck and Steer 1993) are quick, reliable, and valid measures that can be administered at the start of each treatment session to assess the severity of past-week general anxiety and depression. The *Anxiety Sensitivity Index* (Peterson and Reiss 1992) is another useful short questionnaire that can be used to gauge the severity of the patient’s fear of bodily sensations. Scores on this scale can be used to assess whether treatment is altering the patient’s tendency to catastrophically misinterpret bodily sensations. This scale has good reliability and validity, is sensitive to treatment-related effects, and its posttreatment scores predict who is likely to relapse after panic treatment (Taylor 1999).

Another useful questionnaire to monitor treatment progress is the *Panic and Agoraphobia Scale* (Bandelow et al. 2000). This 13-item scale was designed as a short, sensitive measure for treatment outcome studies. The patient is asked to rate the past-week frequency and/or severity of the following: (1) panic attacks, (2) agoraphobia, (3) anticipatory anxiety (i.e., worry about having a panic attack), (4) panic-related disability in various areas of functioning, and (5) worry about the health-related implications of panic (i.e., worry that panic attacks will lead to a heart attack). The Panic and Agoraphobia Scale has good reliability and validity and is sensitive in detecting treatment-related change (Bandelow et al. 2000). It has the advantage of providing a broad assessment of many features of panic disorder and agoraphobia. A limitation is that it does not distinguish between full and limited symptom panic attacks or among the types of panics (i.e., unexpected, situationally bound, situationally predisposed). When asked to recall their attacks, patients may have difficulty making these distinctions. A clinical interview is needed to provide this information.

To gain more detailed information on panic attacks, clinicians and clinical researchers are increasingly including some form of prospective monitoring in their assessment batteries. The most widely used are the *panic attack records*. The patient is provided with a definition of a panic attack and given a pad of panic attack records that can be readily carried in a purse or pocket. The patient is instructed to carry the records at all times and to complete one record (sheet) for each full-blown or limited symptom attack, soon after the attack occurs. Variants on the panic diaries developed by Barlow and colleagues (e.g., Rapee et al. 1990) are among the most informative and easy to use. A version is shown in Figure 69–2, which shows details of one of Sandra’s panic attacks. These records are then reviewed during treatment sessions to glean information about the links among beliefs, bodily sensations, and safety behaviors, and to assess treatment progress.

Sandra reported that the panic attack summarized in Figure 69–2 occurred when she was in a neighborhood supermarket. As she walked down the aisle she looked at the long rows of fluorescent lights and then began to feel mildly depersonalized (see Taylor 2000, Chapter 4, for a discussion of the effects of fluorescent lighting and other environmental triggers on depersonalization). Upon noticing this
sensation, she began to increasingly worry that the depersonalization might become so intense that she would lose all contact with reality, to the point that she would be permanently insane. This greatly frightened her and led to an increase in the intensity of arousal sensations. In an effort to reduce the intensity of the feared depersonalization she averted her gaze from the lights and began studying the list of ingredients on cereal boxes. This distracting safety
behavior calmed her down and reduced the feared depersonalization to the point that she was able to make her way to the express checkout counter and leave with the grocery items she had collected.

Note that the panic attack record serves as a useful memory aid to help patients recall the details and circumstances of their panic attacks. This example shows how the panic attack record helped Sandra recall that she used distraction as a safety behavior. Armed with this information, the therapist could set up exposure exercises to help Sandra learn whether distraction was essential to protecting her from the effects of depersonalization.

### Epidemiology

The lifetime prevalence rate for unexpected panic attacks in the general population ranges between 4 and 12% (Kessler et al. 2006). Investigations of unexpected panic attacks in college student samples using self-report methodology have revealed similar rates, ranging from approximately 5-11% (Asmundson and Norton 1993). The most recent general population estimate of the lifetime prevalence rate for any panic attack, whether unexpected or situationally cued, is 28% (Kessler et al. 2006). The one-year prevalence rate for any panic attack in the general community also vary slightly from lifetime rates, being between 0.2 and 2.1% (Grant et al. 2006, Weissman et al. 1997). In treatment seeking individuals, the prevalence of panic disorder is considerably higher. Approximately 10% of patients in mental health clinics and between 10 and 60% in various medical specialty clinics (e.g., cardiology, respiratory, vestibular) have panic disorder (e.g., Katon 2006). Panic disorder with agoraphobia is more common than panic disorder without agoraphobia in clinical samples (American Psychiatric Association 2000).

### Comorbidity Patterns

Lifetime comorbidity (i.e., the co-occurrence of two or more disorders at any point in a person’s life, regardless of whether or not they overlap) in panic disorder is common, with over 80% of community-dwelling and treatment-seeking patients having had symptoms meeting diagnostic criteria for at least one other anxiety disorder. Estimates of the lifetime prevalence of panic disorder (with or without agoraphobia) range between approximately 1 and 5% in the general population (Grant et al. 2006, Kessler et al. 2006). Weissman et al. (1997) have demonstrated that despite some minor variation, lifetime prevalence rates are generally consistent around the world. One-year prevalence rates in the general community also vary slightly from lifetime rates, being between 0.2 and 2.1% (Grant et al. 2006, Weissman et al. 1997). In treatment seeking individuals, the prevalence of panic disorder is considerably higher. Approximately 10% of patients in mental health clinics and between 10 and 60% in various medical specialty clinics (e.g., cardiology, respiratory, vestibular) have panic disorder (e.g., Katon 2006). Panic disorder with agoraphobia is more common than panic disorder without agoraphobia in clinical samples (American Psychiatric Association 2000).

threshold for at least one other disorder (Kessler et al. 2006). Recent data suggest that the prevalence of lifetime comorbidity in panic disorder with agoraphobia is 100% (Kessler et al. 2006). Comorbidity can pose considerable challenge to treatment. Below, we provide a summary review of the conditions that most often co-occur with panic disorder (also see Table 69–3). The reader is referred to Taylor (2000) for detailed discussion of the various comorbidity models and how they account for the co-occurrence of other disorders with panic disorder.

### Other Anxiety Disorders

The rates of lifetime comorbidity between panic disorder and other anxiety disorders, although variable across epidemiological studies, are high. The most common comorbid anxiety disorders are social phobia and generalized anxiety disorder (15–30%), specific phobia (2–20%), obsessive compulsive disorder (10%), and posttraumatic stress disorder (2–10%) (American Psychiatric Association 2000). To date, there are no studies that have reported comorbid panic disorder and acute stress disorder. The most parsimonious explanation of high comorbidity between panic disorder and the other anxiety disorders is that they share a common diathesis.

### Major Depressive Disorder

Epidemiological studies indicate that major depressive disorder occurs in up to 65% of patients with panic disorder at some point in their lives. In approximately two-thirds of these cases, the symptoms of depression develop along with, or secondary to, panic disorder (American Psychiatric Association 2000). However, since depression precedes panic disorder in the remaining third (Breier et al. 1984), depressive symptoms co-occurring with panic disorder cannot be considered simply as a demoralized response to paroxysms of anxiety. While the risk of developing secondary depression appears to be more closely associated with the severity of agoraphobia than with the severity or frequency of panic attacks, this may be a confound of misdiagnosing some behavioral manifestations of depression as agoraphobia (Taylor 2000). Panic disorder and depression do not appear to be identical disorders (Stein and Uhde 1992) and their co-occurrence may be due to a shared diathesis or mutual exacerbation of symptoms.

### Somatoform and Pain-Related Disorders

Somatoform and pain-related disorders are frequently comorbid with panic disorder. For example, hypochondriasis has been diagnosed in approximately 20% of panic disorder patients attending general medical clinics and in almost 50% of those attending anxiety disorders clinics (Noyes 2001). Acute and chronic musculoskeletal pain (i.e., pain that persists for six months or longer), respectively, are reported by approximately 85 and 40% of panic disorder patients attending anxiety disorders clinics (Asmundson et al. 2001). Irritable bowel syndrome, a condition characterized by persistent abdominal pain and defecation difficulties, co-occurs in 17–41% of treatment seeking panic disorder patients (Lydiard et al. 1994; Noyes et al. 1990). Emerging evidence suggests that comorbidity between panic disorder and both somatoform and pain-related disorders may be best explained by a shared diathesis model (e.g., Asmundson et al., in press).

### Substance Use Disorders

As illustrated in the case of Sandra, panic disorder can be precipitated by the use of psychotropics drugs, with the risk of developing panic disorder increasing with chronic drug use (Louie et al. 1996). Alcohol has been identified as playing a precipitating, maintaining, and aggravating role in panic disorder. The 6-month prevalence of alcohol abuse or dependence in panic disorder has been reported to be 40% in men and 13% in women (Leon et al. 1995). These rates are higher than those observed in people with other anxiety disorders and those with no anxiety disorder (Leon et al. 1995). Although alcohol problems have been reported to precede panic disorder in a majority of cases (Otto et al. 1992), most reports indicate that alcohol problems develop secondary to panic disorder, often as a means of self-medication (Bibb and Chambless 1986). Those having panic disorder with agoraphobia appear to be at greater risk for comorbid alcohol abuse or dependence than those without agoraphobia (Thyer et al. 1986).

### Personality Disorders

Lack of reliable assessment instruments for personality disorders as well as overlapping diagnostic criteria necessarily limit the degree of confidence in reports of comorbidity with panic disorder. Notwithstanding, 40–50% of panic disorder patients have been reported to qualify for one or more personality disorders (American Psychiatric Association 1998), a rate which exceeds that of approximately 10% observed in community control samples (Lenzenweger et al. 2007). The most commonly reported co-occurring personality disorders are avoidant, dependent, and histrionic personality disorders (Taylor and Livesley 1995). These disorders do not co-occur uniquely with panic, also being common in patients with depression and other anxiety disorders, and they often persist despite remission of panic symptoms (Mavissakalian and Hamann 1992). Reasons for comorbidity between panic and personality disorders currently remain unclear.

### Course

Panic disorder symptoms may wax and wane but, if left untreated, the typical course is chronic (American Psychiatric Association 2000). Data from a sample of patients assessed and treated through the Harvard/Brown Anxiety Disorders Research Program and followed prospectively over a 5-year period indicated remission rates in both men and women to be 39% (Yonkers et al. 1998). In general, among those receiving tertiary treatment, approximately 30% of
patients have symptoms that are in remission, 40–50% are improved but still have significant symptoms, and 20–30% are unimproved or worse at 6–10 years follow-up (American Psychiatric Association 2000).

Costs
Panic disorder with or without agoraphobia is associated with impaired occupational and social functioning and poor overall quality of life (Kessler et al., 2006; Leon et al. 1995). People with panic disorder, compared to people in the general population, report poorer physical health (Markowitz et al. 1989). Panic disorder is a leading reason for seeking emergency department consultations (Weissman 1991) and a leading cause for seeking mental health services, surpassing both schizophrenia and mood disorders (Boyd 1986). Panic disorder exceeds the economic costs associated with many other anxiety disorders such as social phobia, generalized anxiety disorder, and obsessive–compulsive disorder (Greenberg et al. 1999). The high medical costs are partly because panic disorder patients quite often present to their primary care physician or hospital emergency departments, thinking they are in imminent danger of dying or “going crazy” (Katernsdahl and Realini 1995). In these settings, patients may undergo a series of extensive medical tests before panic disorder is, if ever, finally diagnosed. Ruling out general medical conditions is good clinical practice but the process contributes substantially to the costs that panic disorder places on health care systems.

Differential Diagnosis
Panic disorder is not diagnosed under several conditions, despite the occurrence of panic attacks. Panic disorder is not diagnosed if panic attacks present only as a feature of other mental disorders; for example, as in situational panic disorder. Panic disorder is unimproved or worse at 6–10 years follow-up (American Psychiatric Association 2000). Instead, diagnoses of anxiety disorder due to a general medical condition, in case of the former, or substance-induced anxiety disorder, in case of the latter, may be appropriate. Because substances are often used as a means of self-medicating for panic attacks, a detailed history can aid in determining whether panic attacks preceded excessive uses of substances, in which case diagnoses of both panic disorder and substance dependence or abuse may be appropriate.

Differences in Developmental, Gender, and Cultural Presentations
Age of onset for panic disorder is distributed bimodally, typically developing between 15 and 19 or 25 and 30 years (Ballenger and Fyer 1996). The clinical features of panic disorder, such as number and severity of symptoms, are much the same across the sexes (Oei et al. 1990). However, women are diagnosed with panic disorder more than twice as often as men (Kessler et al. 2006; Weissman et al. 1997). Recent research indicates that women are more likely to have panic disorder with agoraphobia and that they are more likely to have recurrence of symptoms after remission of their panic attacks than are men (Yonkers et al. 1998). Men, on the other hand, are more likely to have panic disorder without agoraphobia (Yonkers et al. 1998) and are more likely to self medicate with alcohol than are women (Cox et al. 1993). The literature remains unclear as to why these sex differences exist but alludes to the possible role of biological and/or socialization factors (Bekker 1996, Yonkers 1994). Socially prescribed gender roles may be important, such as the widely held social expectation that women should assume the role of homemaker. Consistent with this, agoraphobia is most likely to develop in people who do not need to leave the house in order to work (Mineka and Zinbarg 2006). This may encourage or perpetuate agoraphobic fear and avoidance because the person is not required to confront and thereby overcome their fears.

Panic disorder has been identified across many different cultures, although the expression of the disorder may vary from culture to culture. For example, people with panic disorder in some cultures may be more likely to emphasize the somatic symptoms of their panic attacks, while being reluctant to report cognitive symptoms such as fears of going mad or of losing control. Recent findings suggest that being Native American increases risk, while being Asian, Hispanic, or black decreases risk (Grant et al. 2006).

Etiology and Pathophysiology
Psychological Factors
Cognitive Model—The Vicious Cycle
There are several contemporary cognitive models of panic disorder, which for the most part, are based on variations of the “fear of anxiety” construct. Goldstein and Chambless (1978) proposed that fear of anxiety arises through the association of interoceptive cues with panic attacks. Other words, people with panic disorder are thought to learn to fear the recurrence of aversive panic episodes and thereby develop a fear of panic-related symptoms. Refuting the premise that fear of anxiety develops from the experience of panic attacks, Clark (1986) posited that panic attacks are the product of a tendency to catastrophically misinterpret autonomic arousal sensations that occur in the context of nonpathological anxiety (as well as physical illness, exercise, and ingestion of certain substances). Reiss et al. (1991), incorporating components of the Goldstein and Chambless and Clark models, proposed that panic attacks arise as a consequence of both

1. a predispositional tendency to catastrophically misinterpret and respond with fear to the benign arousal sensations, and
2. a learned fear of anxiety that is maintained by the experience of panic episodes.

More recently, Bouton et al. (2001) have described a variant of the original fear of anxiety model, suggesting that panic disorder develops when exposure to panic attacks
conditions a person to respond with anticipatory anxiety (and sometimes with panic) to internal arousal and contextual cues. While each of these models has proven fruitful in research and treatment contexts, we focus below on the model of Clark (1986).

As described above, Clark (1986) proposes that panic attacks arise from the catastrophic misinterpretation of benign arousal sensations. To illustrate the cognitive processes proposed to underlie panic attacks, consider Sandra’s experience during one of her many attacks. In this instance, she had dizziness sensations stemming from influenza, perceived them as threatening, became aroused, misinterpreted the sensations as being indicative that she was losing her mind, became further aroused with increasing dizziness, had further thoughts of going mad, and spiraled into panic. This vicious cycle is shown in Figure 69–3.

The vicious cycle model makes several assumptions. First, while recognizing that initial panic attacks may be caused by other factors (e.g., drug-related autonomic surges), it assumes that people prone to panic disorder have an enduring tendency to catastrophically misinterpret benign arousal sensations. Second, it assumes that misinterpretations can occur at the conscious and unconscious level (Clark 1988). Third, the cycle can be entered into at any point. For example, the cycle can be initiated by a contextual trigger, such as influenza-related dizziness in the case of Sandra, or simply by having catastrophic thoughts about bodily sensations. Fourth, physiological changes are viewed as one of the several components in a process, rather than as a pathogenic mechanism.

Cognitive models can also account for agoraphobia. Agoraphobia has long been regarded as a product of operant conditioning (Marks 1987). As noted above, it most often develops as a consequence of panic attacks. These attacks typically occur in particular situations (e.g., when in line at a shopping mall, when driving) and motivate the person to avoid or escape these situations. The avoidance and escape behaviors are negatively reinforced by the reduction of aversive autonomic arousal and other anxiety-related sensations. Cognitive factors such as expectations that an attack will be imminent and harmful and that coping will be ineffective play a significant role by influencing and maintaining avoidance behavior (Taylor and Rachman 1994).

A growing body of literature supports the vicious cycle model. Thoughts of imminent catastrophe have been identified as triggers of panic attacks (Taylor 2000). Patients with panic disorder relative to healthy and patient controls have been shown to be

1. characterized by strategic and automatic information processing (i.e., memory, attention) biases for physical threat cues (Mathews and MacLeod 2005),
2. more accurate, in some instances, at detecting body sensations (Zoellner and Craske 1999),
3. more likely to report fear of somatic sensations and beliefs in their harmful consequences (Taylor 1999), and
4. more susceptible to the influence of instructional manipulations of control in response to pharmacological panic provocation challenges, panicking less often under the illusion of greater control in some but not all cases (Barlow 2004).

Research shows that treatments stemming from the cognitive model (reviewed later in this chapter) are effective.

Psychodynamic Models
The most promising psychodynamic models for understanding panic disorder are those that focus specifically on this disorder. Rather than reviewing all the models, we will summarize the model developed by the Cornell Panic-Anxiety Study Group (Milrod et al. 1997, Shear et al. 1993) because it has led to a promising treatment. According to the Cornell group, people at risk for panic disorder have (1) a neurophysiological vulnerability to panic attacks and/or (2) multiple experiences of developmental trauma. These factors lead the child to become frightened of unfamiliar situations and to become excessively dependent on the primary caregiver to provide a sense of safety. The caregiver is unable to provide support always, so the child develops a fearful dependency. This leads, in turn, to the development of unconscious conflicts about dependency (independence versus reliance on others) and anger (expression versus inhibition). The dependency conflict is said to express itself in a number of ways. Some panic-vulnerable people are sensitive to suffocation and overly reliant on others, while others are sensitive to suffocation and overly reliant on a sense of independence. These conflicts can activate conscious or unconscious fantasies of catastrophic danger, which can trigger panic attacks. In addition, the conflicts evoke aversive emotions, such as anxiety, anger, and guilt. The otherwise benign arousal sensations accompanying these emotions can become the focus of “conscious as well as unconscious cognitive catastrophizing” (Shear et al. 1993, p 862), thereby leading to panic attacks.

Neurobiological Factors
Evidence suggests that several neurotransmitter systems, involving neurotransmitters or neuromodulators such as serotonin, noradrenaline, adenosine, gamma-aminobutyric acid, and cholecystokinin-4, play a role in panic disorder (Baldwin 2006). Various brain structures in the limbic system and associated regions have also been implicated. Contemporary biological models of panic, beginning with the pioneering work of Klein (1980), have grown in number and complexity in recent years in an effort to integrate and explain these findings. Recent emphasis has focused on the amygdala, a limbic structure that appears to be involved in coordinating...
the different neurotransmitters involved in anxiety disorders (Goddard and Charney 1997). Today, there is no single, leading biological model of panic. However, there are a number of useful models that guide research and clinical practice (Gorman et al. 2000, Klein 1993). Among the most promising is the neuroanatomical hypothesis recently reviewed by Gorman et al. (2000). This hypothesis is useful for several reasons. First, it integrates a wide range of findings, including animal research and studies of humans. Second, it provides a unifying framework for understanding why panic disorder is associated with so many biological dysregularities such as abnormalities in neurotransmitter systems and irregularities on various indices of autonomic functioning (e.g., Abelson et al. 2001, Cohen et al. 2000). Third, the model accounts for treatment-outcome data, which show that both pharmacological and psychological therapies are effective treatments for panic disorder (as reviewed later in this chapter).

**Neuroanatomical Hypothesis**

Gorman et al. (2000) begin with the observation that there is a remarkable similarity between the physiological and behavioral consequences of panic attacks in humans and conditioned fear responses in animals. Similarities include autonomic arousal, fear evoked by specific cues (i.e., contextual fear), and avoidance of these cues. Animal research indicates that conditioned fear responses are mediated by a “fear network” in the brain, consisting of the amygdala and its afferent and efferent projections, particularly its connections with the hippocampus, medial prefrontal cortex, hypothalamus, and brainstem. Animal studies also show that activation of this network produces biological and behavioral reactions that are similar to those associated with panic attacks. Thus, Gorman et al. (2000) posit that a similar network is involved in panic disorder.

The fear network consists of a complex matrix of interconnections, implicating a number of brain structures and neurotransmitter systems. Sensory input passes through the anterior thalamus to the lateral nucleus of the amygdala. Input is then transferred to the central nucleus of the amygdala, which coordinates autonomic and behavioral responses (LeDoux 2000). Direct sensory input to the amygdala from brainstem structures and the sensory thalamus enables a rapid response to threatening stimuli. The central nucleus of the amygdala projects to the following structures:

1. the parabrachial nucleus, producing an increase in respiratory rate,
2. the lateral nucleus of the hypothalamus, causing autonomic arousal and sympathetic discharge,
3. the locus coeruleus, leading to an increase in norepinephrine and to increases in blood pressure, heart rate, and behavioral fear responses (e.g., freezing),
4. the paraventricular nucleus of the hypothalamus, resulting in an increase in release of adrenocorticoids, and
5. the periaqueductal gray region, leading to avoidance behaviors (Davis and Whalen 2001, LeDoux 2000).

In addition, there are reciprocal connections between the amygdala and the sensory thalamus, prefrontal cortex, insula, and primary somatosensory cortex (Davis and Whalen 2001, LeDoux 2000).

According to Gorman et al. (2000), panic attacks arise from excessive activation of the fear network. In other words, the fear network becomes sensitized (conditioned) to respond to noxious stimuli such as internal bodily sensations and external contexts or situations that the person associates with panic. Sensitization of the network may be manifested by the strengthening of various projections from the central nucleus of the amygdala to brainstem sites (such as the locus coeruleus, periaqueductal gray region, and hypothalamus). The network could be over activated if brainstem inputs to the amygdala are dysregulated. However, autonomic activation (e.g., increased respiration and heart rate) and neuroendocrine activation (e.g., increased cortisol secretion) does not occur in all panic attacks. Moreover, a variety of biological agents with diverse physiological properties can trigger panic attacks in people with panic disorder (e.g., sodium lactate, yohimbine, CO2, caffeine, cholecystokinin-4) (McNally 1994). It is, therefore, unlikely that a single brainstem dysregulation is responsible for panic or, in turn, that brainstem dysregulation is the only way of producing an over-active fear network (Gorman et al. 2000).

Gorman et al. (2000) identify various other ways of activating the fear network. For example, the amygdala receives input from cortical regions involved in the processing and evaluation of sensory information. Therefore, a neurocognitive deficit in these cortico-amygdala pathways could result in the catastrophic misinterpretation of sensory information (i.e., misinterpretation of bodily sensations), leading to an inappropriate activation of the fear network. Notice that this pathway resembles the cognitive model of panic described earlier in this chapter. Thus, the Gorman et al. (2000) model integrates the cognitive model and places it in a neuroanatomical context.

In addition to playing a role in panic disorder, the fear network is thought to play a role in other anxiety disorders and in mood disorders. This is consistent with the comorbidity between panic disorder and these disorders. Abnormalities in the fear network may vary from disorder to disorder. For example, the strength of various connections between components of the network may distinguish various disorders.

Medications, particularly selective serotonin reuptake inhibitors (SSRIs), are thought to desensitize the fear network. This may happen in a number of ways. SSRIs increase serotonergic transmission in the brain (Baldwin 2006). Serotonergic neurons originate in the brainstem raphe and project throughout the central nervous system. Some of these projections have inhibitory influences. For example, the greater the activity in the raphe, the greater the inhibition of noradrenergic neurons in the locus coeruleus, resulting in a reduction of cardiovascular symptoms associated with panic attacks, such as tachycardia (Aston-Jones et al. 1991). Similarly, the greater the activity in the raphe, the greater inhibition in the periaqueductal gray region, resulting in a reduction in avoidance behavior (Viana et al. 1997). Increased serotonergic activity also may reduce hypothalamic release of corticotropin-releasing factor, thereby resulting in a reduction of cortisol (Brady et al. 1992) and a reduction in activity of the locus coeruleus (Butler et al. 1990), thereby leading to a reduction in fear. SSRIs may also directly inhibit activity of the lateral nucleus of the amygdala (Stutzman and LeDoux 1999).
Thus, there appear to be several ways in which SSRIs could desensitize the fear network. Effective psychological therapies are thought to reduce contextual fear and catastrophic misinterpretations at the level of the medial prefrontal cortex and hippocampus.

Given that other neurotransmitter systems have been implicated in panic disorder, it is quite likely that other pharmacologic agents should facilitate the desensitization of the fear network, particularly agents that target more than one of the neurotransmitter systems associated with panic disorder. Consistent with this, there is growing evidence that serotonin noradrenaline reuptake inhibitors (SNRIs) are effective in treating panic disorder (Bradwejn et al. 2005).

Gorman et al.’s (2000) neuroanatomical hypothesis is elegant and comprehensive. However, it is a work in progress and will need to be modified as new findings emerge. Additional brain structures may need to be included in the fear network. For example, a growing body of research suggests that the bed nucleus of the stria terminalis (which is associated with the amygdala) plays an important role in fear (Rosen and Schulkin 1998) and, therefore, should also be included in the fear network.

Genetic Factors
The fear network is thought to be influenced by genetic factors and stressful life events, particularly in early childhood (Gorman et al. 2000). Genetic variants of several candidate genes in neurotransmitter or neurohormonal systems, each with a small individual effect, may contribute to the susceptibility to panic disorder and other anxiety and mood disorders (Leonardo and Hen 2006). Research with monozygotic and dizygotic twins shows that panic disorder is moderately heritable, with 23–43% of variance in liability (Bradwejn et al. 2005).

Vulnerability to panic disorder appears to result from a combination of disorder-specific and disorder-nonspecific factors (Kendler and Prescott 2006). The importance of nonspecific genetic factors is consistent with observation that panic disorder is often comorbid with other disorders. Twin studies suggest that nonspecific factors influence the vulnerability to several disorders, including panic disorder, bulimia nervosa, generalized anxiety disorder, and alcohol dependence (Kendler and Prescott 2006). Genetic factors specific to panic disorder may be those that influence the tendency to catastrophically misinterpret bodily sensations. This cognitive tendency is a distinguishing feature of panic disorder, as described above. Recent twin research indicates that it is moderately heritable in women but not men (Jang et al. 1999). Thus, some specific genetic factors in panic disorder appear to be sex-linked.

Molecular genetic studies have suggested possible candidate genes for conferring risk for panic disorder and other emotional disorders (e.g., genes involved in the regulation of serotonin; Hariri et al. 2006). However, the process of “gene hunting” is slow and laborious, and many of the initial findings have not been replicated in later research (Leonardo and Hen 2006). To complicate matters, a growing body of research suggests that it is not genes per se that are most important, but rather the interaction of particular genes with particular types of environmental events (Moffitt et al. 2006). For example, people possessing one or more copies of the short allele of the serotonin transporter gene, compared to people with two copies of the long allele, are more likely to develop symptoms of anxiety and depression in response to stressful life events (Leonardo and Hen 2006, Moffitt et al. 2006). Further research is required to investigate the possible role of such gene-environment interactions in panic disorder.

Social and Environmental Factors
Environmental events occurring during particular developmental phases such as separation from the primary caregiver during early childhood may activate the genes that modulate the fear network, thereby creating a vulnerability to panic disorder. Research suggests that later events, occurring during adolescence or early adulthood, then precipitate panic disorder in vulnerable individuals. These events may stress the individual at a psychological or physiological level. Events commonly associated with the onset of panic disorder include

1. separation, loss, or illness of a significant other disorder,  
2. being the victim of sexual assault or other forms of interpersonal violence, 
3. financial or occupational stressors, and 
4. intoxication with, or withdrawal from, a psychoactive substance such as marijuana, cocaine, or anesthetic (Taylor 2000).

Treatment
Treatment Goals
Treatment goals as they pertain to panic disorder with and without agoraphobia are, in general, to reduce the frequency and severity of panic attacks, avoidance behavior, and panic-related disability in social and occupational functioning. There are a number of approaches that can be taken in treating panic disorder with and without agoraphobia. Both single and combined treatment modalities are presented in Figure 69–4. According to guidelines from the National Institute for Clinical Excellence (McIntosh et al. 2004), the interventions with the most enduring treatment effects include cognitive-behavioral therapy and particular pharmacotherapies (e.g., SSRIs, imipramine, clomipramine). As noted earlier, SNRIs are also promising treatments. Of the various treatments for panic disorder, high potency benzodiazepines are effective in the short term but are less effective in producing long-term remission of panic disorder (Cloos 2005, McIntosh et al. 2004).

Psychosocial Treatments
Cognitive–Behavioral Therapy (CBT)
CBT treatment packages include a number of components, such as psychoeducation (e.g., information about the cognitive model of panic), breathing retraining, cognitive restructuring, relaxation exercises, interoceptive exposure, and situational exposure (Taylor 2000). Breathing retraining involves teaching the patient to breathe with the diaphragm rather than with the chest muscles. Cognitive restructuring focuses on challenging patient’s beliefs about the dangerousness of bodily sensations (e.g., challenging the belief that palpitations lead to heart attacks).

Interoceptive exposure involves inducing feared bodily sensations to further teach patients that the sensations are
harmless. For example, Sandra’s treatment involved interoceptive exposure exercises that induced depersonalization. Several tasks were used, including (1) staring at a ceiling fluorescent light for 1 minute, (2) staring at her reflection in the mirror for 2 minutes, and (3) staring at a spot on the wall for 3 minutes. Multiple tasks were used in order to promote the generalization of treatment effects (i.e., to help her learn that depersonalization was harmless regardless of how it arises).

Situational exposure involves activities that bring the patient into feared situations such as shopping malls, bridges, or tunnels. In Sandra’s case, situational and interoceptive exposure were combined. She was asked to visit a lighting store to spend time inspecting the various fluorescent lamps. Exposure exercises are often framed as “behavioral experiments” to test patients’ beliefs about the catastrophic consequences of arousal-related sensations. Sandra’s exposure exercises helped her test the belief that depersonalization leads to permanent insanity. The exercises were also used to help her test the alternative, noncatastrophic belief that depersonalization is an unpleasant but harmless experience.

---

Figure 69–4 A decision tree for treating panic disorder.
A common practice in CBT is to encourage patients to refrain from engaging in safety behaviors. Prior to treatment, Sandra typically engaged in distraction whenever she was exposed to depersonalization-inducing stimuli such as fluorescent lights. The CBT therapist encouraged her to refrain from distraction so she could learn that depersonalization is harmless, even when it becomes intense. Evidence suggests that reducing safety behaviors improves treatment efficacy (Taylor 2000). Despite the advantages of exposure exercises, they are medically contraindicated in some cases. For example, a hyperventilation exercise would not be used in a patient with severe asthma (Taylor 2000).

A large body of evidence shows that CBT is effective in reducing panic attacks, agoraphobia, and associated symptoms such as depression (Barlow 2004, Taylor 2000). However, not all CBT interventions may be necessary. Interoceptive exposure, situational exposure, and cognitive restructuring are the most widely used and supported interventions. Several studies suggest that breathing retraining reduces panic frequency. However, recent research casts doubt about the importance of hyperventilation in producing panic attacks. This suggests that breathing retraining may only be useful for a minority of patients, for which chest breathing or hyperventilation plays a role in producing panic symptoms. Breathing retraining may be counterproductive if it prevents patients from learning that their catastrophic beliefs are unfounded. Given these concerns, breathing retraining should be used sparingly in the treatment of panic disorder. If used at all, the clinician should ensure that the patient understands that breathing exercises are used to remove unpleasant but harmless sensations. Interoceptive exposure and cognitive restructuring are important for helping patients learn that the sensations are not dangerous.

How effective is CBT compared to other therapies? A small but growing literature suggests that the efficacy of CBT is equal to or greater than that of alprazolam and imipramine at posttreatment (Barlow 2004, Taylor 2000). Future research is needed to compare CBT to other pharmacotherapies, such as SSRIs. Preliminary evidence suggests that CBT is effective in treating patients who have failed to respond to pharmacotherapies (e.g., Heldt et al. 2006). Follow-up studies suggest that CBT is effective in the long term and is likely to be more effective than short-term pharmacological treatment. It is not known whether drug treatments would be as effective as CBT if patients remained on their medications. Any conclusions about the long-term efficacy of panic treatments are necessarily tentative because patients sometimes seek additional treatment during the follow-up interval.

Other Psychosocial Interventions
Several other approaches have been used in the treatment of panic disorder, including psychodynamic psychotherapies (e.g., Milrod et al. 2000), hypnosis (e.g., Delmonte 1995), Eye Movement Desensitization and Reprocessing (EMDR) (Shapiro 1995), and mindfulness meditation (Miller et al. 1995). Support for these treatments is limited, largely to case studies and uncontrolled trials. Controlled studies (Feske and Goldstein 1997), although few in number, indicate that hypnosis and EMDR are of limited value in treating panic disorder. When used to treat this disorder, these treatments may be no better than placebo (Taylor 2000). Interventions that look more promising are mindfulness meditation (Miller et al. 1995) and psychodynamic psychotherapies modified to specifically focus on panic symptoms (Milrod et al. 2000). However, none have been extensively evaluated as panic treatments and none have been compared to empirically-supported treatments such as CBT or SSRIs.

Pharmacological Treatments
Controlled studies show that effective anti-panic medications include tricyclic antidepressants (e.g., imipramine), monoamine oxidase inhibitors (MAOIs; e.g., phenelzine), high-potency benzodiazepines (e.g., alprazolam), SSRIs (e.g., fluvoxamine), and SNRIs (e.g., venlafaxine). According to the available research, these treatments seem to have broadly similar efficacy, at least in the short term, although there is some evidence that SSRIs tend to be most effective (Boyer 1995, Taylor 2000). The classes of medication differ in their side effects and their contraindications. Anticholinergic effects (e.g., blurred vision, dry mouth) are common problems with tricyclics. They are also contraindicated in patients with particular comorbid cardiac disorders. Dietary restrictions (i.e., abstaining from foods containing tyramine) are a limitation of many MAOIs. Sedation, impaired motor coordination, and addiction are concerns with benzodiazepines (Taylor 2000).

When efficacy and side effects are considered together, SSRIs (and possibly SNRIs) emerge as the most promising drug treatments for panic disorder. However, even SSRIs have side effects, with the most problematic being a short-term increase in arousal-related sensations (Pohl et al. 1988). To overcome this problem, SSRIs can be started at a low dose (e.g., 5–10 mg/d for paroxetine; 12.5–25 mg/d for sertraline) and then increased gradually (e.g., up to 10–50 mg/d for paroxetine; up to 25–200 mg/d for sertraline). The choice of SSRI is determined on the basis of several factors, including side effects, patient preference, and the patient’s history of responding (or not responding) to particular agents.

For drug refractory patients, or patients who are unable to tolerate SSRI side effects, combination medications are sometimes used. For example, SSRIs can be augmented with benzodiazepines or other agents (Bandelow and Eckart 2004). Benzodiazepines can be used to dampen the side effects of SSRIs. Despite some positive preliminary reports supporting this strategy, its value in the treatment of panic disorder remains to be properly evaluated. An alternative strategy is to change the patient’s medication. Another approach to the drug refractory patient is to use a psychosocial treatment such as CBT, as an alternative or adjunctive intervention. These approaches are discussed in more detail later in this chapter.

Combined Treatments
Simultaneous Treatments
Many clinicians believe the optimal treatment consists of drugs combined with some form of psychosocial intervention (Black 2006). This view arose from observations that even the most effective drugs and the most effective psychosocial interventions do not eliminate panic disorder in all cases. It was thought that combination treatments might be a way to improve treatment outcome. The available evidence provides mixed support for this view, and currently
it is unclear whether combining CBT with medication is more effective than either treatment alone (Pull 2007). In fact, there is evidence that combined treatment might lead to worse outcome (Black 2006).

To illustrate these findings, several studies have compared CBT to CBT combined with imipramine. These results have been mixed. Adding imipramine in the range of 150–300 mg/day to either situational exposure or CBT sometimes improves treatment outcome in the short-term, provided that patients are able to tolerate the dose (Barlow 2004, Taylor 2000). Any advantage of combined treatment tends to be lost at follow-up. Similarly, studies of combining CBT with SSRIs (fluvoxamine or paroxetine) have produced mixed results, with some studies finding the combination is no better than CBT alone, others finding that the combination is most effective, and yet others finding the combination to be most effective for some symptoms but not others. Methodological limitations of these studies might account for the inconsistent findings, and more research is needed on this important topic (Black 2006, Taylor 2000).

The neuroanatomical model (Gorman et al. 2000), with its dual emphasis on cognitive and serotonergic mechanisms, suggests that this combined treatment might be superior to CBT alone and to SSRIs alone. Yet pharmacotherapies such as SSRIs might undermine the patient's confidence in implementing CBT; particularly if they attribute their gains to medications rather than to their own efforts at using the skills learned in CBT. Large, well-designed studies are needed to explore these important issues.

Sequential Treatments
A more promising type of combined therapy is a sequential approach, where patients are treated with pharmacotherapy during the acute phase, and then are treated with CBT as the medication is phased out. Several studies have shown that adding CBT during the tapering period for alprazolam and clonazepam reduces the relapse rate associated with these drugs (see Taylor 2000, for a review). It remains to be demonstrated that CBT can reduce relapse when patients are tapered off other antipanic drugs such as SSRIs. However, there is no reason to expect that CBT would not be helpful in these cases.

Issues in Clinician–Patient Relationship
Regardless of whether the patient is treated with a psychosocial intervention or with medication, it is important to develop a sound clinician-patient relationship. A thorough assessment of the patient’s problems is an important first step to establishing such a relationship, because a good assessment (combined with feedback of the results) gives the patient confidence that the clinician has a good understanding of the presenting problems. A sound working relationship is also facilitated when the clinician exhibits interpersonal warmth and is nonjudgmental. Patients with panic disorder are sometimes ashamed or embarrassed about their symptoms, especially if the patient views anxiety as a sign of personal weakness (Taylor, 2000). To this end it can be important for the clinician to point out that the patient has been exhibiting courage in all of his or her attempts to enter feared situations. The important message to convey is that courage is defined as persistence in the face of fear, regardless of whether or not the fears are excessive.

Patients with panic disorder may also be ashamed of the catastrophic beliefs (or images) they experience during their panic attacks. Typically, there is a state-dependency in the strength of these beliefs; during a panic attack the patient may be completely convinced in the veracity of the belief (e.g., “My heart is beating so rapidly that I’m bound to have a heart attack”), whereas in the calmer moments the patient may seriously question the veracity of the belief (e.g., “As I sit here in your office, it seems silly to think that palpitations will harm my heart, because my cardiologist has told me that my heart is fine”). Thus, when the patient is relatively calm in the clinician’s office, the patient may be reluctant to discuss panic-related catastrophic beliefs because he or she currently views the beliefs as foolish or embarrassing. To circumvent this problem the clinician can educate the patient about the state-dependency of beliefs, and point out that sometimes even highly implausible beliefs can seem very convincing when the person is in the midst of panic. Such information conveys acceptance to the patient, thereby strengthening the therapeutic relationship and encouraging the patient to be more open about revealing catastrophic beliefs. In turn, this can facilitate treatment, especially CBT in which it is important to identify catastrophic beliefs. To illustrate, once this state-dependency in belief strength had been explained, and the clinician had provided information about the sometimes bizarre nature of panic-related catastrophic beliefs, one of our patients was able to reveal that many of her panic attacks were triggered by feelings of sexual arousal, accompanied by the terrifying belief that the arousal would never end and she would become permanently incapacitated.

A sound therapeutic relationship is also important for maximizing adherence to pharmacologic treatments. If the patient trusts the clinician, and is provided with relevant information about the benefits and likely side effects of a given drug, then the patient is likely to persist with taking the medication, even when unpleasant, temporary side effects are experienced. Although a sound therapeutic relationship is important for medication adherence, it may not be enough. It is often important for the clinician to identify any erroneous or unrealistic beliefs that the patient might have about taking psychotropic medication (e.g., “Drugs will turn me into an emotional automaton,” or “Psychiatric drugs are a form of brain washing”). Cognitive restructuring, as used in CBT, can be applied to such beliefs in order to facilitate treatment adherence (Taylor, 2000).

Treatment Refractory Patients
In the previous sections of this chapter, we noted that one useful strategy for treatment refractory panic disorder is to try an alternative treatment, such as switching from pharmacotherapy to CBT (Heldt et al. 2006) or switching from one drug to another. There are several other important strategies for improving treatment response. If the patient has received an adequate course of treatment—such as a drug at an adequate dose for a sufficient period of time, or CBT for a sufficient number of sessions—then treatment failure might be the result of an erroneous or inadequate case formulation. The clinician might have misdiagnosed panic disorder and implemented panic treatment in a case in which the panic-like symptoms were actually due to a general medical condition. For example, one of us (ST)
learned of a case in which a psychiatric resident was using CBT to treat a patient who appeared to have panic disorder with agoraphobia. Over the course of treatment, the patient became somewhat less concerned about the dangerousness of her symptoms, and became less avoidant, but her panic-like symptoms persisted unabated. The unsatisfactory response to treatment led the resident and supervisor to reassess the patient in order to identify the source of the problem. It turned out that the patient actually did not have panic disorder; she was suffering from the effects of a pheochromocytoma.

For cases of genuine panic disorder in which there is an unsatisfactory treatment response, treatment outcome may be improved by using more than one treatment. As noted earlier in this chapter, it is currently unclear whether combining medications with CBT improves outcome for the average patient, although this strategy may possibly be useful in particular cases. Drug augmentation strategies could also be used, such as combining an SSRI or tricyclic antidepressant with a high potency benzodiazepine such as alprazolam or clonazepam (Bandelow and Eckart, 2004).

Special Factors Influencing Treatment
In addition to the issues discussed above, patient preference is an important factor in determining treatment success; if a patient strongly prefers one particular treatment (e.g., CBT) and is given a non-preferred treatment (e.g., an SSRI), then treatment refusal, treatment non-adherence, or dropout may occur (Taylor, 2000). Also, given the fact that panic disorder is commonly comorbid with other disorders, there may be cases in which it is more important to treat one of the co-occurring disorders (e.g., a comorbid substance use disorder, a mood disorder associated with significant suicide risk, or personality disorder associated with self-harming behaviors) before a course of panic treatment should be contemplated.

Comorbid general medical conditions can also influence the selection and nature of panic treatment. For example, some cardiac conditions may contraindicate the use of particular medications (e.g., tricyclics). Patients with particular general medical conditions may be unable to safely complete some of the exercises used in CBT. For instance, some forms of interoceptive exposure (e.g., voluntary hyperventilation) may be contraindicated for panic patients who also have particular general medical conditions (e.g., poorly controlled epilepsy or severe asthma). These issues in treatment selection are discussed in more detail in Taylor (2000).

Finally, one of the most important issues influencing treatment selection concerns the problem of availability of suitably qualified clinicians. In many countries, or regions of countries, there is a dearth of clinicians with CBT expertise (typically psychologists) and a shortage of clinicians with psychopharmacology expertise (typically psychiatrists). Under such circumstances the burden of treating panic disorder typically falls upon the shoulders of the general practitioner or primary care physician. Here, treatment options typically consist of pharmacotherapy, combined with a few simple CBT exercises (e.g., graded exposure to feared situations). Such treatments may be beneficial for many patients with panic disorder, although a substantial proportion of patients will require specialist treatment (Bandelow and Eckart 2004, Taylor 2000). While in-person access to a specialist is not feasible, telephone and Internet administered CBT is a promising, empirically-supported option (e.g., Calbrin et al. 2005).

Comparison of DSM-IV-TR and International Classification of Diseases, Tenth Revision (ICD-10) Diagnostic Criteria
The ICD-10 Diagnostic Criteria for Research for a panic attack are identical to the DSM-IV-TR criteria set except that ICD-10 includes an additional symptom (dry mouth). In contrast to the DSM-IV-TR algorithm, which does not give special weight to any particular symptom, the ICD-10 algorithm requires that at least one of the symptoms be palpitations, sweating, trembling, or dry mouth. Like DSM-IV-TR, ICD-10 requires recurrent panic attacks but, in contrast to DSM-IV-TR, it does not include a criterion requiring that the panic attacks be clinically significant.

The ICD-10 Diagnostic Criteria for Research for Agoraphobia differ markedly from the DSM-IV-TR criteria. The ICD-10 specifies that there can be fear or avoidance of at least two of the following situations: crowds, public places, traveling alone, or traveling away from home. Furthermore, ICD-10 requires that at least two symptoms of anxiety (from the list of 14 panic symptoms) be present together on at least one occasion and that these anxiety symptoms be “restricted to, or predominate in, the feared situations or contemplation of the feared situations.” In contrast, DSM-IV-TR Agoraphobia is defined in terms of “anxiety about being in places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having an unexpected or situationally predisposed panic attack.” No specific avoided situations or specific types of anxiety symptoms are required for a diagnosis.

Introduction
The experience of fear and the related emotion of anxiety are universal and familiar to everyone. Fear exists in all cultures and appears to exist across species. Presumably, the purpose of fear is to protect an organism from immediate threat and to mobilize the body for quick action to avoid danger. Emotion theorists consider fear to be an alarm response that fires in the presence of imminent threat or danger. The function of the primarily noradrenergic-mediated fear response is to facilitate immediate escape from threat (flight) or attack on the source of threat (fight) (Barlow 1991, 2002). Therefore, fear is often referred to as a fight-or-flight response (Cannon 1929). All the manifestations of fear are consistent with its protective function. For example, heart rate and breathing rate increase to meet the increased oxygen needs of the body, increased perspiration helps to cool the body to facilitate escape, and pupils dilate to enhance visual acuity.

Anxiety, on the other hand, is a future-oriented mood state in which the individual anticipates the possibility of threat and experiences a sense of uncontrollability focused on the upcoming negative event. In the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000), anxiety is defined as “the apprehensive anticipation of future danger or misfortune accompanied by a feeling of dysphoria or somatic symptoms of tension” (p. 820). If one were to put anxiety into words, one might say, “Something bad might happen soon. I am not sure I can cope with it but I have to be ready to try.” Anxiety is primarily mediated by the gamma-aminobutyric acid-benzodiazepine system (Barlow 1991, 2002).

Despite evidence that fear and anxiety are mediated by different brain systems, anxiety and fear are related, which makes sense ethologically. Experiencing anxiety after encountering signals of impending danger seems to lower the threshold for fear that is triggered when danger actually occurs (e.g., being attacked by a mugger or almost being hit by an automobile). Anxiety leads to a shift in attention toward the source of danger so that individuals become more vigilant for relevant threat cues and therefore are more likely to experience fear in the face of perceived immediate threat.

Fear and anxiety are not always adaptive. At times, the responses can occur in the absence of any realistic threat or out of proportion to the actual danger. Almost everyone has situations that arouse anxiety and fear despite the fact that the actual risk is minimal. It is not unusual to become anxious before a job interview or a speech. Many individuals feel fearful when exposed to situations such as dental visits, seeing certain animals, or being at certain heights. For some people, these fears reach extreme levels and may cause significant distress or impairment in functioning. It is at this point that what we typically refer to as shyness and fearfulness might meet diagnostic criteria for social phobia or specific phobia, respectively (see DSM-IV-TR Criteria 300.23 and 300.29).

As discussed later in this chapter, phobias are the most common of the anxiety disorders and are among the most common of all mental disorders. However, despite the frequency with which phobias occur in the general population, they have tended to be relatively ignored by clinicians and researchers. In the case of social phobia, it was not until the publication of the Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) (American Psychiatric Association 1980) that the diagnostic category was created. The introduction of social phobia to the diagnostic nomenclature has led to a slow but steady increase in research on the disorder, so that social phobia
has now become a popular topic of study among researchers on anxiety disorders. In addition to being widespread, social phobia is associated with significant functional impairment. Individuals with social phobia experience impairment in their work, home, and social relationships (Antony et al. 1998b). Also, social phobia often presents comorbidly with other mental disorders. Despite the high prevalence rate and significant impairment, generalized social phobia is rarely diagnosed or treated in a primary care setting and is often dismissed as extreme shyness (Heimberg 2003). For example, Katzelnick et al. (2001) found that only 0.5% of patients with generalized social phobia were accurately diagnosed even though over 44% had made a visit to a mental health specialist or had been prescribed antidepressants.

With respect to specific phobias, the lack of attention is probably due to several factors. First, many physicians and researchers may view specific phobias to be less severe than other disorders, therefore warranting less attention. In addition, few individuals with specific phobias present for treatment, and the ones who do seek help tend to differ from untreated individuals with phobias with respect to the number and types of specific phobias (Chapman et al. 1993). As with social phobia, there has been an increase in attention paid to specific phobias, along with increased recognition that these phobias can interfere seriously with an individual’s ability to function. It is not unusual for flying phobias to lead individuals to refuse job promotions that involve travel or to avoid visiting distant family members. Likewise, individuals with insect phobias may avoid being outside during the summer.

**Diagnosis**

Social phobia and specific phobias have both overlapping and distinguishing diagnostic and clinical features. The next section reviews the definitions and diagnostic features of the disorders as well as assessment methods. An overview of the clinical features of the disorders includes their epidemiology, comorbidity patterns, and course. Issues related to establishing a differential diagnosis are considered followed by an examination of differences in developmental, gender, and cultural presentations.

**Definition and Diagnostic Features**

In the DSM-IV-TR (American Psychiatric Association 2000), social phobia (also known as social anxiety disorder) is defined as a “marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny of others.” Typical situations feared by individuals with social phobia include meeting new people, interacting with others, attending parties or meetings, speaking formally, eating or writing in front of others, dealing with people in authority, and being assertive. Specific phobia is defined as a “marked and persistent fear that is excessive or

---

### DSM-IV-TR Diagnostic Criteria for 300.23

**Social Phobia (Social Anxiety Disorder)**

**A.** A marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny by others. The individual fears that he or she will act in a way (or show anxiety symptoms) that will be humiliating or embarrassing. Note: In children, there must be evidence of the capacity for age-appropriate social relationships with familiar people and the anxiety must occur in peer settings, not just in interactions with adults.

**B.** Exposure to the feared social situation almost invariably provokes anxiety, which may take the form of a situationally bound or situationally predisposed panic attack. Note: In children, the anxiety may be expressed by crying, tantrums, freezing, or shrinking away from social situations with unfamiliar people.

**C.** The person recognizes that the fear is excessive or unreasonable. Note: In children, this feature may be absent.

**D.** The feared social or performance situations are avoided or else are endured with intense anxiety or distress.

**E.** The avoidance, anxious anticipation, or distress in the feared social or performance situation(s) interfere significantly with the person’s normal routine, occupational (or academic) functioning, or social activities or relationships, or there is marked distress about having the phobia.

**F.** In individuals under age 18 years, the duration is at least 6 months.

**G.** The fear or avoidance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition and is not better accounted for by another mental disorder (e.g., panic disorder with or without agoraphobia, separation anxiety disorder, body dysmorphic disorder, a pervasive developmental disorder, or schizoid personality disorder).

**H.** If a general medical condition or another mental disorder is present, the fear in criterion A is unrelated to it, e.g., the fear is not of stuttering, trembling in Parkinson’s disease, exhibiting abnormal eating behavior in anorexia nervosa or bulimia nervosa.

**Specify if:**

**Generalized:** if the fears include most social situations (also consider the additional diagnosis of avoidant personality disorder)
specification may be appropriate.

Finally, for both disorders the fear must not be better accounted for by another problem. For example, an individual with obsessive–compulsive disorder who fears contamination from contact with injections would not receive an additional diagnosis of specific phobia unless there were additional concerns about injections that were unrelated to contamination (e.g., fear of fainting during an injection, fear of pain from the needle). Each diagnosis has specifiers or subtypes to allow for the provision of more specific diagnostic information. For social phobia, the psychiatrist can specify whether the phobia is generalized (i.e., includes most social situations). For specific phobias, the psychiatrist can indicate which one of five types best describes the focus of the phobia: animal, natural environment, blood—innjection—injury, situational, or other.

### Specific Phobia Phenomenology and Subtypes

As discussed earlier, DSM-IV-TR defines five main types of specific phobia: animal, natural environment, blood—injection—injury, situational, and other. These types were introduced on the basis of a series of reports to the DSM-IV-TR Anxiety Disorders Work Group (Curtis et al. 1990) showing that specific phobia types tend to differ on a variety of dimensions including age at onset, sex composition, patterns of covariation among phobias, focus of apprehension, timing and predictability of the phobic response, and type of physiological reaction during exposure to the phobic situation.

Although anxiety about physical sensations and the occurrence of panic is a feature typically associated with panic disorder, several studies have shown that panic-focused and symptom-focused apprehensions are not unique to panic disorder and agoraphobia. In fact, individuals with specific

#### Specific Phobia

A. Marked and persistent fear that is excessive or unreasonable, cued by the presence or anticipation of a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).

B. Exposure to the phobic stimulus almost invariably provokes an immediate anxiety response, which may take the form of a situationally bound or situationally predisposed panic attack. **Note:** In children, the anxiety may be expressed by crying, tantrums, freezing, or clinging.

C. The person recognizes that the fear is excessive or unreasonable. **Note:** In children, this feature may be absent.

D. The phobic situation(s) is avoided or else is endured with intense anxiety or distress.

E. The avoidance, anxious anticipation, or distress in the feared situation(s) interferes significantly with the person’s normal routine, occupational (or academic) functioning, or social activities or relationships, or there is marked distress about having the phobia.

F. In individuals under age 18 years, the duration is at least 6 months.

G. The anxiety, panic attacks, and phobic avoidance associated with the specific object or situation are not better accounted for by another mental disorder, such as obsessive-compulsive disorder (e.g., fear of dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., avoidance of stimuli associated with a severe stressor), separation anxiety disorder (e.g., avoidance of school), social phobia (e.g., avoidance of social situations because of fear of embarrassment), panic disorder with agoraphobia, or agoraphobia without history of panic disorder.

**Specify type:**

- **Animal type**
- **Natural environment type** (e.g., heights, storms, water)
- **Blood-injection-injury type**
- **Situational type** (e.g., airplanes, elevators, enclosed places)
- **Other type** (e.g., fear of choking, vomiting, or contracting an illness; in children, fear of loud sounds or costumed characters)

---

Phobias score a full standard deviation above the mean for normal persons on the Anxiety Sensitivity Index (Reiss et al. 1986), a questionnaire that measures anxiety related to experiencing the physical sensations of fear. In other words, individuals with specific phobias may report anxiety about the sensations (e.g., racing heart, breathlessness, dizziness) typically associated with their fear. Also, there is evidence that in addition to fearing danger from the phobic object (e.g., a plane crash, being bitten by a dog) many individuals with specific phobias fear danger or negative consequences as a result of their reaction in the phobic situation such as crashing the car in response to panic symptoms or being embarrassed by others noticing their anxiety symptoms (McNally and Steketee 1985). Also, the few relevant studies that have been conducted suggest that there may be differences in sensation-focused apprehension across specific phobia types.

Data are converging to indicate that individuals with phobias from the situational (e.g., claustrophobia) and blood–injury–injection types may be especially internally focused on their fear (Antony et al. 1997a). Whereas individuals with situational phobias tend to fear the possible consequences of panic, those with blood–injury–injection phobias seem uniquely concerned about sensations that indicate that fainting is imminent (e.g., lightheadedness, hot flashes).

Specific phobia types may differ with respect to timing and predictability of the phobic response as well. One study based on retrospective self-reports found that individuals with phobias of driving, enclosed places, and blood–injury were more likely to report that their fear was delayed in the phobic situation than were those with animal phobias (Craske et al. 1993). These data suggest that delayed and unpredictable panic attacks may be more characteristic of situational phobias than of other phobia types, consistent with the argument that situational phobias share more features with agoraphobia than do other specific phobia types. This is supported by the finding that individuals with situational phobias report more unexpected panic attacks than do individuals with other specific phobia types (Lipsitz et al. 2002).

Perhaps the most consistent difference among specific phobia types is the tendency for individuals with blood–injury–injection phobias to report a history of fainting in the phobic situation. Although all phobia types are associated with panic attacks in the phobic situation, only patients with blood and injection phobias report fainting (Antony et al. 1997b). Specifically, individuals with blood–injury–injection phobias experience a diphasic physiological response, which includes an initial increase in arousal followed by a sharp drop in heart rate and blood pressure that can lead to fainting. This response occurs at times in approximately 70% of people with blood phobias and 50% of those with injection phobias and seems to be unique to situations involving blood and medical procedures (Öst 1992). In other words, people who faint in these situations still show the usual type of response (i.e., increased arousal) in other situations that they fear (e.g., heights, flying, etc.). Disgust has been identified as a potential mediator of faintness associated with blood–injury–injection stimuli (Exeter-Kent and Page 2006).

The different responses experienced in different phobias have been explained from an evolutionary perspective. As mentioned earlier, the typical phobic responses of fear and panic are adaptive in that the increased arousal facilitates escape. In contrast, the most adaptive response during serious injury may be a drop in blood pressure to prevent excessive bleeding. It has been suggested that this response is mediated by an overactive sinoaortic baroreflex that is triggered by heightened arousal in situations involving blood or needles (Adler et al. 1991). Of course, in people with blood and injection phobias, the response is excessive and unwarranted, as there is typically no danger of excessive blood loss.

Social Phobia Phenomenology and Subtypes

Many researchers in the area of social phobia tend to classify the disorder into two main subtypes. DSM-IV-TR requires that diagnosticians specify whether a social phobia diagnosis is “generalized,” or includes most social situations. In addition, a “discrete or circumscribed” subtype is often used by investigators to describe patients with only one domain of social anxiety, usually involving performance-related situations (e.g., public speaking).

Several studies have examined differences among these subtypes. Specifically, patients with generalized social phobia tend to be younger, less educated, and less likely to be employed than are patients with discrete social phobia. In addition, generalized social phobia is associated with more depression, anxiety, general distress, and concerns about negative evaluation from others (Heimberg et al. 1990a, Turner et al. 1992). Discrete social phobia appears to be associated with greater cardiac reactivity.

Heimberg et al. (1993a) have suggested that a third subtype, called “nongeneralized” social phobia, be added to describe patients who (1) may or may not have discrete social fears, (2) report significant anxiety in situations involving social interaction, and (3) have at least one social domain in which they do not experience significant anxiety. An example of an individual with nongeneralized social phobia would be a person who functions well at work but feels anxious when meeting new people at casual parties and other situations outside of work. Although the nongeneralized subtype was not adopted in DSM-IV-TR, it has been evaluated in several research studies. In studies comparing generalized and nongeneralized social phobia, individuals with generalized social phobia tend to be more likely to have additional psychiatric diagnoses, poorer social skills, more functional impairment, poorer performance on a social interaction role play test, earlier age at onset, and more social avoidance than those with nongeneralized social phobia (Herbert et al. 1992). In addition, patients with generalized social phobia describe themselves as more shy and describe their families as more overprotective and less likely to socialize with others, compared to people with nongeneralized social phobia (Bruch and Heimberg 1994).

Several other methods of subtyping social phobia have been attempted as well (e.g., Holt et al. 1992). Overall, it appears that social phobia can take a variety of different forms. Further research is needed to determine if the DSM-IV-TR method of classifying the subtypes of social phobia can be improved. In a move away from subtyping social phobia, Hofmann et al. (2004) recently proposed a dimensional model based on the finding that individuals with social phobia are actually a heterogeneous group. According to this model, individuals with social phobia...
may be best characterized along a dimensional continuum of emotional response and behavioral tendencies. Proposed dimensions include fearfulness, anxiousness, shyness, self-consciousness, submissiveness, and anger. Further work is necessary to investigate the utility of this dimensional approach.

**Assessment**

As is the case with most disorders, a comprehensive assessment is important in helping the psychiatrist to decide which treatment approach is most appropriate for a given patient. In the case of specific and social phobias, a thorough evaluation should include a structured or semistructured interview, self-report measures, and a behavioral assessment. Each of these measures provides different types of information that may be relevant to later treatment decisions. This section provides an overview of relevant assessment issues. Additional comprehensive reviews may be found elsewhere (McCabe and Antony 2002, Rowa et al. in press).

During all parts of the initial evaluation, the psychiatrist should be sensitive to several issues. First, for many patients with phobias, even discussing the phobic object can provoke anxiety. For example, some patients with spider phobias experience panic attacks when they discuss spiders. Some patients with blood phobias faint when they discuss surgical procedures. Therefore, the psychiatrist should ask the patient whether discussing the phobic object or situation will provoke anxiety. If the interview is likely to be a source of stress, the psychiatrist should emphasize the importance of the information that is being collected, as well as the potential therapeutic value of discussing the feared object. As described in a later section, exposure to the feared stimulus is an essential component of the treatment of most specific phobias. Of course, the psychiatrist should use his or her judgment when deciding how much to push the patient in the first session. For treatment to be effective, establishing a trusting therapeutic relationship early in the course of treatment is essential.

With respect to social phobia, the assessment itself may be considered a phobic stimulus. Because individuals with social phobia fear the evaluation of others, a psychiatric interview may be especially frightening. Even completing self-report questionnaires in the waiting room may be especially frightening. Even completing self-report questionnaires in the waiting room may be difficult for patients who fear writing in front of others. The psychiatrist should be sensitive to this possibility and provide reassurance when appropriate.

Both specific phobia and social phobia may be associated with skills deficits that may have an impact on treatment. For example, social phobia is often associated with impairment in social skills such as poor eye contact (e.g., Spence et al. 1999). Individuals with a specific phobia of driving may lack basic driving skills and would benefit from driving lessons. Thus, a comprehensive assessment should include assessment of skills deficits relevant to the disorder so that treatment planning can include a skills training component.

**Structured and Semistructured Interviews**

Although there are numerous structured and semistructured interviews available (Summerfeldt and Antony 2002), two of the most commonly used interviews for diagnosing anxiety disorders are the Anxiety Disorders Interview Schedule for DSM-IV-TR (ADIS-IV) (Brown et al. 1994) and the Structured Clinical Interview for Axis I DSM-IV-TR Disorders—Patient Edition (SCID-I/P for DSM-IV-TR) (First et al. 2001). Current and lifetime diagnoses of specific phobia and social phobia based on the ADIS-IV have been shown to have good to excellent reliability for the specific phobia types and the generalized type of social phobia (Brown et al. 2001b). To date, there are few published studies on the psychometric properties of the SCID-I for DSM-IV-TR. One study (Zanarini et al. 2000) found that the reliability (both interrater and test–retest) for social phobia was in the fair to good range and the reliability for other Axis I disorders was also good. Previous versions of the SCID-I for the DSM-III-R have been shown to be reliable, especially for phobic disorders (Antony and Swinson 2000a, Summerfeldt and Antony 2002). Each interview has advantages and disadvantages. Although the SCID-I provides detailed assessment of a broader range of disorders relative to the ADIS-IV (including eating disorders and psychotic disorders), the ADIS-IV provides more detailed information on each of the anxiety disorders and, like the SCID-I, includes sections to provide DSM-IV-TR diagnoses for the mood disorders and other disorders that are typically associated with the anxiety disorders (e.g., substance use and somatoform disorders). In addition, the ADIS-IV includes more questions to help differentiate specific and social phobias from other disorders with which they share features. Both the SCID-I and ADIS-IV are available in versions for use with children, adolescents, and their parents (for review, see Grills and Ollendick 2002).

**Self-Report Measures**

Numerous self-report measures have been created for the assessment of specific phobias and social anxiety. The main advantage of self-report measures is the time that they save for the psychiatrist. Relevant self-report measures are recommended before the clinical interview if possible. This will allow the interviewer to follow up specific responses during the interview. Measures can be administered again, periodically, to assess progress and outcome. It should be noted that questionnaire measures do not always correlate highly with performance on behavioral measures (Klieger and Franklin 1993). Furthermore, there is evidence that men are more likely than women to underestimate their fear on specific phobia measures (Pierce and Kirkpatrick 1992). The Fear Survey Schedule (Geer 1965, Wolpe and Lang 1964) is a commonly used measure for screening for various specific phobia types. However, the more recently developed Phobic Stimuli Response Scales (Cutshall and Watson 2004) may be more psychometrically sound, especially for assessing fears of blood–injury, animals, and physical confinement, as well as fears of social situations. In addition, a variety of measures exist to assess fear of specific objects and situations. For example, the Mutilation Questionnaire (Klorman et al. 1974) is a popular test for assessing fear of situations involving blood and medical procedures. Self-report measures for assessing both specific phobia and social anxiety are listed in Table 70–1. Detailed reviews of these and other measures are available (Antony et al. 2001b, McCabe and Antony 2002, Rowa et al. in press). For a review of child measures, see Ollendick et al. 2004).

Behavioral Tests

Behavioral testing is an important part of any comprehensive evaluation for a phobic disorder. This is particularly the case if behavioral or cognitive–behavioral treatment will be used. Because most individuals with phobias avoid the objects and situations that they fear, patients may find it difficult to describe the subtle cues that affect their fear in the situation. In addition, it is not unusual for patients to misjudge the amount of fear that they typically experience in the phobic situation. A behavioral approach test can be useful for identifying specific fear triggers as well as for assessing the intensity of the patient’s fear in the actual situation.

To conduct a behavioral approach test, patients should be instructed to enter the phobic situation for several minutes. For example, an individual with a snake phobia should be instructed to stand as close as possible to a live snake and note the specific cues that affect his or her fear (e.g., size of snake, color, movement) and the intensity of the fear (perhaps rating it on a 0– to 100-point scale). Patients should pay special attention to their physical sensations (e.g., palpitations, sweating, blushing), negative thoughts (e.g., “I will fall from this balcony”), and anxious coping strategies (e.g., escape, avoidance, distraction).

The behavioral approach test will help in the development of a specific treatment plan. However, before treatment patients will often be reluctant to enter the feared situation. If this is the case, the information collected during the behavioral approach test may be elicited during the early part of behavioral treatment.

Epidemiology

As discussed earlier, specific phobia and social phobia are among the most common psychiatric disorders and the most common of the anxiety disorders. Data from the National Comorbidity Survey Replication (NCS-R) (Kessler et al. 2005b) yielded lifetime prevalence estimates of 12.5% for specific phobias and 12.1% for social phobia in an epidemiological survey of over 9000 individuals aged 18 years and older from across the United States, based on DSM-IV-TR diagnostic criteria. The original NCS study (Kessler et al. 1994) reported similar findings based on DSM-III-R criteria with lifetime prevalence rates of 11.3% for specific phobias and 13.3% for social phobia. Table 70–2 lists lifetime prevalence rates for particular specific fears and phobias based on findings of the original NCS (Curtis et al. 1998), with phobias of animals and heights being the most frequently diagnosed specific phobias.

Results from epidemiological studies (Bourdon et al. 1988, Curtis et al. 1998) show that most specific phobias are more common in women than in men, although there are differences in sex ratio among phobia types. Specifically, the ratio of females to males is smaller for height phobias than for other specific phobia types. For social phobia situations, sex differences are less pronounced than for most specific

phobia types. In the NCS (Kessler et al. 1994), relatively small sex differences in social phobia prevalence were confirmed, with lifetime estimates of 11.1% for males and 15.5% for females. In addition, the relatively equal numbers of men and women with social phobia in epidemiological studies is consistent with findings from samples of individuals presenting for treatment (Hofmann and Barlow 2002).

The onset of social phobia is typically during childhood and adolescence, with a range of 13–24 years in clinical studies and 10–16.6 years in epidemiological studies (Wittchen and Fehm 2003). Although later onset (after age 25) does occur, it is rare, and most often secondary to a separate Axis I disorder such as depression or an eating disorder (Wittchen and Fehm 2003). The NCS-R survey yielded a median age of onset for social phobia of 13 years with 50% of the sample reporting onset between age 8 and age 15 (Kessler et al. 2005a). This is supported by research findings that social phobia is common in children and is diagnosed in a significant percentage of children referred to a specialty anxiety disorders clinic (Albano et al. 1995).

A history of childhood anxiety has been associated with an earlier age of onset of social phobia as well as greater severity and comorbidity (Otto et al. 2001). Mean age at onset for specific phobias appears to differ depending on the type of phobia. Phobias of animals, blood, storms, and water tend to begin in early childhood whereas phobias of heights tend to begin in the teens (Curtis et al. 1990), and phobias of the situational type (e.g., claustrophobia) begin even later, with mean ages at onset in the late teens to middle twenties (Curtis et al. 1990, Lipsitz et al. 2002). The NCS-R survey yielded a median age of onset for specific phobia of 7 years with 50% of the sample reporting onset between age 5 and age 12 (Kessler et al. 2005a).

Comorbidity Patterns
The issue of comorbidity has received increasing attention in the years since the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) (American Psychiatric Association 1987), was published. Before that time, the diagnostic decision rules in DSM-III were arranged hierarchically, such that having one diagnosis precluded the assignment of other diagnoses lower on the hierarchy. According to DSM-III-R and DSM-IV-TR, patients may receive multiple diagnoses. The issue of comorbidity is important for several reasons. First, covariation among disorders provides valuable information about the nature of specific disorders as well as the utility of current diagnostic nomenclature. For example, high rates of co-occurrence between two disorders could reflect overlap in the definitions of two disorders (as may be the case with social phobia and avoidant personality disorder) or shared etiological pathways. In addition, comorbidity may have implications for treatment. For example, an individual with social phobia who abuses alcohol might be less likely to benefit from treatment for social phobia if the alcohol abuse affects compliance with the social phobia treatment.

Specific Phobia
One of the variables considered by the DSM-IV-TR Anxiety Disorders Work Group in its decision to classify specific phobias by types was the pattern of covariation observed among specific phobias within each of the four main types (Curtis et al. 1990). For example, about 70% of individuals with blood phobias tend to have injection phobias as well (Ost 1992). In addition, numerous factor analytical studies have found that blood–injection–injury phobias tend to cluster together as do animal phobias, natural environment phobias, and situational phobias (e.g., Liddell et al. 1991).

In other words, having a phobia of one specific phobia type makes an individual more likely to have additional phobias of the same type than of other types. However, the clustering is not perfect; many studies show exceptions to this pattern (Curtis et al. 1998) and it has been argued that assigning specific phobias to types may not be diagnostically useful for a number of reasons (Antony et al. 1997b). Research on the classification of specific phobia types is inconsistent. For example, in several of these studies, height phobias tend to be associated with situational phobias (e.g., claustrophobia), despite height phobias being listed as an example of the natural environment type in DSM-IV-TR (Muris et al. 1999). Furthermore, it is not always clear where a particular phobia should be assigned. Is a phobia of dentists an example of a blood–injection–injury phobia or does it fall into the “other” type? Finally, it has been argued (Antony et al. 1997b) that simply naming the phobia (e.g., specific phobia, choking) is more informative and clinically useful than using the type classification “specific phobia, other type.”

Specific phobias tend to co-occur with other specific phobias. One study found that 76% of a sample of 915 individuals with a lifetime history of specific phobias had at least one or more additional specific phobias (Curtis et al. 1998). This finding is consistent with research showing that individuals with specific phobias often report multiple fears on a fear survey (Hofmann et al. 1997). However, other research indicates that comorbid phobias may not be as prevalent (Fredrikson et al. 1996) and that numbers in previous studies may have been inflated by a lack of discrimination between multiple phobias and fears of multiple situations that are accounted for by a single phobia. For example, an individual may fear bridges, elevators, and flying due to a fear of heights. In this case, the multiple situations represent one specific phobia rather than multiple phobias. A recent methodologically rigorous study found that 15% of patients with a principal diagnosis of specific phobia also met criteria for another type of specific phobia (Brown et al. 2001a).

In addition, specific phobias often co-occur with other DSM-IV-TR disorders. A recent study found that 33% of patients presenting with a principal diagnosis of specific phobia had additional symptoms that met criteria for an Axis I anxiety or mood disorder (Brown et al. 2001a). However, compared with individuals who have other anxiety disorders, individuals with principal diagnoses of a specific phobia are less likely to have additional diagnoses. Rather, specific phobias typically occur on their own or as additional diagnoses of lesser severity than the principal diagnosis. For example, in one study, specific phobias occurred in about 27% of individuals with panic disorder and agoraphobia, in 16% of individuals with generalized anxiety disorder, and in 3–9% of individuals with other DSM-III-R disorders (Moras et al. 1995). Other studies confirm that specific phobias are a frequently occurring additional diagnosis, particularly with other anxiety disorders (Curtis et al.
1998, Goisman et al. 1995). However, specific phobias tend to occur less frequently in the context of other disorders such as depression (Schatzberg et al. 1998) and alcohol use disorders (Lehman et al. 1998).

Whereas the above-mentioned studies reflect “syndrome” comorbidity, one can also discuss comorbidity at the “symptom” level. In other words, one can examine the frequency with which specific fears are associated with disorders regardless of whether they meet criteria for specific phobia. One study examined the rate of subclinical specific fears (i.e., those not meeting a clinical threshold for distress or functional impairment) in a sample of patients with anxiety disorders (Antony et al. 1994). In this study, specific fears were the most frequently assigned subclinical diagnoses, with 28% of these patients reporting subclinical fears. In fact, almost half of all subclinical diagnoses assigned were specific fears. In summary, it appears that specific phobias commonly occur as additional diagnoses, at both clinical and subclinical levels.

**Social Phobia**

Social anxiety is a feature of many disorders. Individuals with panic disorder, obsessive–compulsive disorder, or eating disorders often avoid social situations because of the possibility of being judged negatively if their symptoms are noticed by others. However, to meet diagnostic criteria for social phobia, one’s concerns must not be exclusively related to the symptoms of another disorder. With this criterion in mind, social phobia still tends to be associated with a variety of other DSM-IV-TR disorders. Furthermore, unlike specific phobias, social phobia is frequently associated with additional disorders of lesser severity. It is estimated that 50–80% of patients with social phobia have at least one other mental disorder, most commonly other anxiety disorders, major depressive disorder, and substance abuse disorders (Fehm et al. 2005, Wittchen and Fehm 2003). The presence of comorbid mood disorders has been associated with a greater duration of social phobia as well as more severe impairment (Erwin et al. 2002). Other studies have found that panic disorder with or without agoraphobia, generalized anxiety disorder, posttraumatic stress disorder, major depressive disorder, and substance abuse are common additional diagnoses as well (Brown et al. 2001a, Kessler et al. 2005b, Mannin et al. 2000, Van Ameringen et al. 1991). In one prospective study, an estimated relative risk ratio of 2.30 for alcohol abuse or dependence was found in individuals with subclinical social phobia relative to individuals without social phobia or subclinical social fears, suggesting that individuals with subclinical social phobia were more than twice as likely to develop alcohol use disorders than were individuals without social phobia or subclinical social anxiety (Crum and Pratt 2001).

As an additional diagnosis, social phobia is often assigned in patients with panic disorder with agoraphobia, generalized anxiety disorder, obsessive–compulsive disorder, and major depressive disorder (Brown et al. 2001a). Social phobia is also common among patients with eating disorders (Schwalberg et al. 1992) and alcohol abuse (Riemann 1993) as well. In a study examining comorbidity in eating disorders, 20% of the sample had a lifetime diagnosis of social phobia (Kaye et al. 2004). When social phobia coexists with a mood disorder, substance abuse disorder, or another anxiety disorder, the social phobia tends to predate the other disorder (Van Ameringen et al. 1991). Treatment of these disorders should include components that address the social phobia when both disorders occur together.

**Course**

As discussed earlier, the mean age at onset of social phobia is in the middle teens. The age at onset of specific phobias varies depending on the phobia type, with phobias of animals, blood, storms, and water tending to begin in early childhood, phobias of heights beginning in the teens, and situational phobias beginning in the late teens to middle twenties. Although childhood fears are often transient (e.g., most children outgrow fear of the dark without treatment), fears that persist into adulthood usually have a chronic course unless treated.

Although many phobias begin after a traumatic event, many patients do not recall the specific onset of their fear, and few empirical data exist regarding the initial period after the fear onset. Clinically, however, some patients report a sudden onset of fear, whereas others report a more gradual onset. Studies examining the onset of phobias have tended to assess the onset of the fear rather than the onset of the phobia (i.e., the point at which the fear creates significant distress or functional impairment). A study by Antony et al. (1997b) suggests that the fear and phobia onset are often not the same. Patients with specific phobias of heights, animals, blood–injection, or driving were asked to estimate the earliest age at which they could recall having their fear and the earliest age at which they could recall experiencing distress or functional impairment due to their fear. As shown in Table 70–3, phobias began at an average of 9 years after the fear onset. Anecdotally, the types of factors leading to the transition from fear to phobia included gradual increases in the intensity of fear, additional traumatic events (e.g., panic attacks, car accidents), increased life stress, and changes in living situation (e.g., starting a job that requires exposure to heights). Similarly, it is not unusual for individuals with social phobia to report having been shy as children, although their anxiety may not have reached phobic proportions until later.

The impact of specific phobia on quality of life has received little attention (Mogotsi et al. 2000). However, evidence suggests that specific phobia may be associated with significant psychosocial impairment (Essau et al. 2000). Social phobia is associated with a high degree of impairment and disability that increases over time (Fehm et al. 2005, Wittchen and Fehm 2003). For example, in one study, one fifth of patients with social phobia had clinically severe impairment in quality of life defined as being two more standard deviations below the community norm (Rapaport et al. 2005). One factor that may contribute to impairment in social performance for individuals with social phobia is the use of safety behaviors (Stangier et al. 2006).

**Differential Diagnosis**

Social anxiety is associated with a variety of DSM-IV-TR disorders. Similarly, several disorders other than specific phobia are associated with fear and avoidance of circumscribed stimuli. Therefore, accurate diagnosis of specific and social phobias depends on a thorough understanding of the DSM-IV-TR criteria and knowledge of how to distinguish these disorders from related conditions. Correct
diagnosis depends on being able to evaluate the patient’s focus of apprehension, reasons for avoidance, and range of situations feared.

Panic disorder with agoraphobia may easily be misdiagnosed as social phobia or a specific phobia (especially the situational type). For example, many patients with panic disorder avoid a variety of social situations because of anxiety about having others notice their symptoms. In addition, some individuals with panic disorder may avoid circumscribed situations, such as flying, despite reporting no other significant avoidance. Four variables should be considered in making the differential diagnosis: (1) type and number of panic attacks, (2) focus of apprehension, (3) number of situations avoided, and (4) level of anxiety outside of the phobic situation.

Patients with panic disorder experience unexpected panic attacks and heightened anxiety outside of the phobic situation, whereas those with specific and social phobias typically do not. In addition, individuals with panic disorder are more likely than those with specific and social phobias to report fear and avoidance of a broad range of situations typically associated with agoraphobia (e.g., flying, enclosed places, crowds, being alone, shopping malls). Finally, patients with panic disorder are typically concerned only about the possibility of panicking in the phobic situation or about the consequences of panicking (e.g., being embarrassed by one’s panic reactions). In contrast, individuals with specific and social phobias are usually concerned about other aspects of the situation as well (e.g., being hit by another driver, saying something foolish).

Consider two examples in which the differential diagnosis with panic disorder might be especially difficult. First, individuals with claustrophobia are typically extremely concerned about being unable to escape from the phobic situation as well as being unable to breathe in the situation. Therefore, like patients with panic disorder and agoraphobia, they usually report heightened anxiety about the possibility of panicking. The main variable to consider in such a case is the presence of panic attacks outside of claustrophobic situations. If panic attacks occur exclusively in enclosed places, a diagnosis of specific phobia might best describe the problem. In contrast, if the patient has unexpected or unced panic attacks as well, a diagnosis of panic disorder might be more appropriate.

A second example is a patient who avoids a broad range of situations feared on busy streets, and various social situations including parties, meetings, and public speaking. Without more information, this patient’s problem might appear to meet criteria for social phobia, panic disorder with agoraphobia, or both diagnoses. As mentioned earlier, patients with panic disorder often avoid social situations because of anxiety about panicking in public. In addition, patients with social phobia might avoid situations that are typically avoided by individuals with agoraphobia for fear of seeing someone that they know or of being observed by strangers. To make the diagnosis in this case, it is necessary to assess the reasons for avoidance.

It may be difficult to distinguish among types of specific phobias. For example, is a bridge phobia best considered a situational type (i.e., driving) or a natural environment type (i.e., heights)? This decision should be based on the context of the bridge phobia. If the individual fears falling or fears other high places, a height phobia may be the appropriate diagnosis. In contrast, if bridges are one of many driving-related situations that the person fears, a driving phobia might be more appropriate.

Other diagnoses that should be considered before a diagnosis of specific phobia is assigned include posttraumatic stress disorder (PTSD) (if the fear follows a life-threatening trauma and is accompanied by other PTSD symptoms such as reexperiencing the trauma), obsessive–compulsive disorder (if the fear is related to an obsession, e.g., contamination), hypochondriasis (if the fear is related to a belief that he or she has some serious illness), separation–anxiety disorder (if the fear is of situations that might lead to separation from the family, e.g., traveling on an airplane without one’s parents), eating disorders (if the fear is related to a fear of choking), and psychotic disorders (if the fear is related to a delusion).

Social phobia should not be diagnosed if the fear is related entirely to another disorder. For example, if an individual with obsessive–compulsive disorder avoids social situations only because of the embarrassment of having others notice her or his excessive hand washing, a diagnosis of social phobia would not be given. Furthermore, individuals with depression, schizoid personality disorder, or a pervasive developmental disorder may avoid social situations because of a lack of interest in spending time with

Note: PDA, panic disorder with agoraphobia. “Fear” refers to the age at which the fear began for individuals with specific phobias or the age at which panic attacks began for individuals in the panic disorder with agoraphobia (PDA) group. “Phobia” refers to the age at which the fear began to cause significant distress or functional impairment for the specific phobia groups or the age at which the individuals with PDA met full criteria for the disorder. “Difference” was calculated by subtracting ages of onset for the specific phobia groups or the age at which the individuals with PDA met full criteria for the disorder. Differences were significant at $p < .05$. $^*$ $p < .01$. $^{**} p < .001$.

others. To be considered social phobia, an individual must avoid these situations specifically because of anxiety about being evaluated negatively.

In the case of generalized social phobia, the diagnosis of avoidant personality disorder may be considered. However, most studies suggest that the differences between avoidant personality disorder and social phobia are more quantitative than qualitative and that the former may simply be a more severe form of the latter (Ralevski et al. 2005, Widiger 1992). Therefore, most patients who meet criteria for avoidant personality disorder will meet criteria for social phobia as well. Some researchers have proposed that the diagnosis of social phobia is preferred to that of avoidant personality disorder given that a personality disorder diagnosis should be ruled out when it includes significant features of an Axis I disorder (Wittchen and Fehm 2003).

Finally, social and specific phobias should be distinguished from normal states of fear and anxiety. Many individuals report mild fears of circumscribed situations or mild shyness in certain social situations. Others may report intense fears of public speaking or heights but insist that these situations rarely arise and that they have no interest in being in these situations. For the criteria for a specific or social phobia to be met, the individual must report significant distress about having the fear or must report significant impairment in functioning.

A variety of factors should be considered in deciding whether a patient’s fear exceeds the threshold necessary for a diagnosis of specific or social phobia. To make the differential diagnosis between normal fears and clinical phobias, the psychiatrist should consider the extent of the individual’s avoidance, the frequency with which the phobic stimulus is encountered, and the degree to which the individual is bothered by having the fear. For example, an individual who fears seeing snakes in the wild but who lives in the city, never encounters snakes, and never even thinks about snakes would probably not be diagnosed with a specific phobia. In contrast, when an individual’s fear of snakes leads to avoidance of walking through parks, camping, swimming, and watching certain television programs, despite having an interest in doing these things, a diagnosis of specific phobia would be appropriate.

Similar factors should be considered in deciding at what point normal shyness reaches an intensity that warrants a diagnosis of social phobia. An individual who is somewhat quiet in groups or when meeting new people but does not avoid these situations and is not especially distressed by his or her shyness would probably not receive a diagnosis of social phobia. In contrast, an individual who frequently refuses invitations to socialize because of anxiety, quits a job because of anxiety about having to talk to customers, or is distressed about her or his social anxiety would be likely to receive a diagnosis of social phobia.

Diagnostic decision trees for social and specific phobias are presented in Figures 70–1 and 70–2.

Differences in Developmental, Gender, and Cultural Presentations
For both assessment and treatment planning, it is important to consider variations in disorder features and phenomenology across developmental stages, gender, and cultural background.

Developmental Differences
Several studies have begun to look at the prevalence of phobias across the life span. Little is known about the prevalence of phobias among elderly persons, although there is some evidence that the prevalence of phobic disorders may decrease slightly after age 65 years (Eaton et al. 1991).

Among children, specific and social fears are common (Straus and Last 1993). Because these fears may be transient, DSM-IV-TR has included a provision that social and specific phobias not be assigned in children unless they are present for more than 6 months. In addition, children may be less likely than adults to recognize that their phobia is excessive or unrealistic. The specific objects feared by children are often similar to those feared by adults, although children may be more likely to fear objects and situations that are not easily classified in the four main specific phobia types in DSM-IV-TR (e.g., balloons or costumed characters). In addition, children often report specific and social phobias having to do with school. Children with social phobia tend to avoid changing for gym class in front of others, eating in the cafeteria, or speaking in front of the class. They may stay home sick on days when frightening situations arise or may make frequent trips to the school nurse. Whereas some investigators have found that boys and girls are equally likely to present for treatment of phobias (Straus and Last 1993), others have found social phobia to be more common among girls than boys (Anderson et al. 1987). In one prospective study of childhood anxiety disorders, Last et al. (1996) found that almost 70% of children with a specific phobia were recovered over a 3- to 4-year period compared to a recovery rate of 86% for social phobia. Thus, almost a third of the clinical sample with specific phobia had symptoms that still met clinical criteria for specific phobia at the end of the follow-up period. This was the lowest recovery rate among the anxiety disorders that were studied. However, those in the clinical sample with specific phobia had the lowest rate of development of new psychiatric disorders (15%) compared to the other anxiety disorders studied (e.g., the rate of development for new psychiatric disorders was 22% for those in the clinical sample with social phobia).

Gender Differences
As mentioned earlier, specific phobias tend to be more common among women than men (e.g., Curtis et al. 1998). This finding seems to be strongest for phobias from the animal type, whereas sex differences are smaller for height phobias and blood–injury–injection phobias. In addition, social phobia tends to be slightly more prevalent among women than men, although these differences are relatively small (Antony and Swinson 2000a, Fehm et al. 2005).

There are several reasons why women may be more likely than men to report specific phobias. First, as discussed earlier, there is evidence that men tend to underreport their fear (Pierce and Kirkpatrick 1992). Also, women may be more likely than men to seek treatment for their difficulties, which would account for the fact that sex differences are often larger in treatment samples compared with epidemiological samples. In addition, as discussed later, sex ratios for phobias differ across cultures, which may be explained by cultural differences in treatment seeking. Finally, the sex difference in prevalence may reflect actual differences between men and women in susceptibility to develop phobias.
Women and men are taught to deal differently with typical phobic stimuli. Traditionally, boys more than girls are often encouraged to play with spiders and toy snakes and to engage in more adventurous activities (e.g., hiking in high places). In addition, women may have more role models for the development of fear than men do. Images of women standing on chairs when they see a mouse or running away from spiders are common in children's cartoons and other media, but men are rarely depicted as being frightened by these objects. Therefore, it is possible that in Western cultures women learn to fear certain situations more strongly than do men. Of course, it is difficult to know whether culture and the media are responsible for sex differences or whether they simply reflect differences that exist for other reasons (e.g., different predisposing factors). It will be interesting to see whether sex ratios for phobias change as traditional gender roles continue to evolve.

One study examining sex differences and social phobia found significant gender differences in the presentation of social phobia (Turk et al. 1998). Whereas men were more fearful than women of urinating in public bathrooms and returning items to a store, women were more fearful than men of a number of situations including talking to people in authority, public speaking, being the center of attention, expressing disagreement, and throwing a party. Sex differences were not found in terms of comorbidity, social phobia subtypes, or duration of illness.

**Cultural Differences**

Little is known about cultural differences in specific and social phobias. Several reasons have been suggested for this lack of relevant data. First, individuals from minority cultures in the United States tend to underuse traditional mental health facilities and are more likely than other groups to terminate treatment after one session (Sue 1990). When African-Americans seek mental health services, they may be more likely to present to a physician, minister, or community mental health clinic than a university hospital, which is where much of the research tends to take place (Neal and Turner 1991). In addition, certain minority groups may be less likely to participate in psychological research because of the negative ways in which research data have historically
been used to affect government policies toward minority groups (Neal and Turner 1991).

Nevertheless, a few studies bear on the issue of cultural differences in phobias. For example, there is evidence from epidemiological studies that African-Americans are 1.5–3 times as likely as whites to report phobic disorders, even after controlling for education and socioeconomic status (Brown et al. 1990, Curtis et al. 1998, Warheit et al. 1975). Several explanations for this finding have been provided. For example, some of the fears reported by African-American individuals may reflect realistic concerns that were misdiagnosed as phobias. For example, African-American persons in inner city communities may have more realistic reasons to fear violence (Warheit et al. 1975). Furthermore,
African-Americans experience more negative evaluation from others, and some of their social concerns may be realistic. Another possibility is that African-Americans experience more chronic stress than do whites and therefore may be more susceptible to the development of phobias and other problems. Finally, there may be cultural differences in response biases on questionnaire measures of fear and during interviews (Brown et al. 1990).

Other research has found that specific phobias are more common among US-born Mexican-Americans than in US-born whites or immigrant Mexican-Americans, after controlling for sex, age, socioeconomic status, and various other variables (Karno et al. 1989, Vega et al. 1998). No group differences emerged for the prevalence of social phobia across these groups (Karno et al. 1989). Some of the factors mentioned (e.g., differences in stress and response biases) may explain the differences between whites and Mexican-Americans born in the United States. In addition, it has been suggested that “selective migration” may account for the relatively low rate of phobias in immigrant Mexican-Americans. In other words, individuals with specific phobias may be less likely to emigrate.

A variety of studies have shown that specific phobias, social phobia, and related conditions exist across cultures. For example, in Japan, a condition exists called taijin kyôfu in which individuals have an “obsession of shame.” This condition has much overlap with social phobia in that it is often accompanied by fears of blushing, having improper facial expressions in the presence of others, looking at others, shaking, and perspiring in front of others (Takahashi 1989). In addition, studies have identified individuals with social and specific phobias in a variety of other non-Western countries including Saudi Arabia (Bassiony 2005, Chaleby 1987), Israel (Iancu et al. 2006), India (Raguram and Bhide 1985), Japan (Kleinknecht et al. 1997, Sakurai et al. 2005), and other East Asian countries (Chang 1997, Lee and Oh 1999). Interestingly, in some other cultures, the sex ratio for phobias tends to be reversed. For example, in studies from Saudi Arabia and India, up to 80% of individuals reporting for treatment of phobias were male. Similarly, in Japan about 60% of patients with taijin kyôfu are male. In the case of phobias in India, it has been suggested that traditional gender roles may account for the difference in treatment seeking in Indian men and women (Raguram and Bhide 1985). Specifically, Indian women are often discouraged from leaving the house alone or conversing with others without the husband’s permission. It is difficult to know how cultural expectations affect sex differences in phobias in other cultures.

Psychiatrists treating patients from different cultures should be aware of cultural differences in presentation and response to treatment. For example, there is some evidence that although Asian Americans and European Americans report a similar number of events that evoke anxiety in social situations, Asian Americans report more negative emotions in social situations than do European Americans (Lee et al. 2006). In a review of culture-specific strategies in counseling, Sue (1990) summarized data on cultural differences in verbal communication styles, proxemics (i.e., use of interpersonal space), nonverbal communication, and other verbal cues (e.g., tone and loudness). Many cues that a psychiatrist might use to aid in the diagnosis of social phobia in white Americans may not be useful for diagnosing the condition in other cultures. For example, although many psychiatrists interpret a lack of eye contact as indicating shyness or a lack of assertiveness, avoidance of eye contact among Japanese and Mexican-Americans is often viewed as a sign of respect, according to Sue (1990).

In contrast to white Americans, Japanese are apparently more likely to view smiling as a sign of embarrassment or discomfort. Furthermore, cultural differences in tone and volume of speech may lead psychiatrists to misinterpret their patients. For example, whereas white Americans often are uncomfortable with silence in a conversation, British and Arab individuals may be more likely to use silence for privacy and other cultures use silence to indicate agreement among the parties or a sign of respect. In addition, Asian individuals have been reported to speak more quietly than white Americans, who in turn speak more quietly than those from Arab countries. Therefore, differences in the volume of speech should not be taken to imply differences in assertiveness or other indicators of social anxiety.

Treatment methods may have to be adapted for different cultures. For example, the direct style of many cognitive and behavioral therapists may be more likely to be perceived as rude or insensitive by individuals with certain cultural backgrounds than those with other backgrounds. It should be noted that individuals within a culture differ on these variables just as individuals across cultures differ. Therefore, although psychiatrists should be aware of cultural differences, these differences should not blind the psychiatrist to relevant factors that are unique to each individual patient.

**Etiology and Pathophysiology**

The etiology of both social and specific phobia is complex and involves an interaction of biological, psychological, and social/environmental factors. This next section provides a review of etiological pathways and pathophysiology.

**Genetic Factors**

Specific phobia and social phobia tend to run in families. It appears that being a first-degree relative of an individual with a specific phobia puts one at a greater risk for a specific phobia compared with first-degree relatives of never mentally ill controls (31% versus 11%). However, the particular phobia that is transmitted is usually different from that in the relative, although it is often from the same general type (e.g., animal, situational). Furthermore, relatives of people with specific phobias are not at increased risk for other types of anxiety disorders (including social phobia) or subclinical fears (Fyer et al. 1990). The results of studies examining genetic transmission of different phobia subtypes have been mixed. In one twin study, Kendler et al. (1999) found heritability estimates of 47% for animal phobias, 59% for blood–injection–injury phobias, and 46% for situational phobias. Others studies have not supported a genetic component in the development of natural environment and situational fears (e.g., Skre et al. 2000). The heritability of blood and injection phobias may be even greater than that for other phobias. One study found that 61% of individuals with blood phobia and 29% of those with injection phobias reported having a first-degree relative with the same fear (Öst 1992). However, these findings should be interpreted...
with caution because relatives did not undergo independent interviews.

Findings for individuals with social phobia and their families show a similar pattern. In one study, 16% of first-degree relatives of individuals with social phobia had symptoms that met criteria for social phobia, whereas only 5% of first-degree relatives of never mentally ill control individuals had social phobia (Fyer et al. 1993). Other research has found that the relative risk for generalized social phobia is approximately ten times higher in first-degree relatives of individuals with generalized social phobia than in first-degree relatives of a control group without social phobia (Stein et al. 1998a).

Of course, the existence of a disorder in multiple family members does not necessarily imply genetic transmission. Family members often share learning experiences and other environmental factors. To establish a genetic relationship among family members with a particular disorder, twin studies, adoption studies, and molecular genetics studies are typically conducted. Currently, there are no adoption or molecular genetics studies of social or specific phobias, and twin studies have yielded conflicting results.

A twin study by Skre et al. (1993) found that although many of the anxiety disorders have a strong genetic component, in the case of specific and social phobias, environmental influences seem to be most important. In contrast, Andrews et al. (1990) found a genetic contribution to the development of neurotic traits and symptoms that may predispose individuals to develop anxiety disorders in general, but not a particular anxiety disorder. This study included individuals with social phobia but not specific phobias. Another twin study examining genetic transmission of both specific and social phobias found heritability estimates of 51% for social phobia, 47% for animal phobias, 59% for blood-injection-injury phobias, and 46% for situational phobias (Kendler et al. 1999). Consistent with previous research (Page and Martin 1998), individual-specific environmental influences (e.g., experiencing a traumatic event in the phobic situation) were found to be etiologically significant in the development of both social and specific phobias but family-specific environmental influences (e.g., shared environment) were not (Kendler et al. 1999). In another genetic study of specific and social phobias conducted by Kendler et al. (1992), both genetic and individual-specific environmental factors (e.g., phobia-specific traumatic event) were influential in the development of specific phobia, whereas for social phobia, both genetic and nonspecific environmental factors have an etiological role. More recently, Hettema et al. (2005) found that social phobia loaded on to a genetic factor shared with generalized anxiety disorder, panic, and agoraphobia whereas specific phobias loaded onto a separate uncorrelated genetic factor.

Although there are conflicting findings on whether there is a general genetic factor (influencing risk for any anxiety disorder) or a specific genetic factor (influencing risk for specific anxiety disorders such as specific and social phobias), some general conclusions can be made. In the case of social phobia, there seems to be a moderate (based on the strength of the correlations from twin studies) disorder-specific genetic influence combined with specific and nonspecific environmental influences. In the case of specific phobia, evidence supports a disorder-specific genetic contribution combined with disorder-specific environmental influences (e.g., traumatic conditioning experiences involving the phobic object or situation). The underlying structure of the genetic and environmental risk factors is similar between men and women for both social phobia and specific phobia (Hettema et al. 2005).

Although the nature of the genetic contribution has yet to be specified (a low threshold for alarm reactions or vasovagal responses is one possibility), specific and social phobias may be related to personality factors that have been found to be highly heritable. For example, fear of negative evaluation, a cognitive construct central to the phenomenology of social phobia, has been found to be moderately heritable (48%) in a twin study conducted by Stein et al. (2002). Two broader personality traits that may be relevant are neuroticism (or emotionality) and extroversion (or sociability) (Plomin 1989). Average heritability estimates for these traits are about 50% across a wide range of genetic studies. Emotionality probably predisposes individuals to develop a range of anxiety and mood disorders whereas sociability may be most relevant to social phobia. Furthermore, certain phobias may have other specific genetic contributions. Up to 70% of individuals with blood phobia report a history of fainting on exposure to blood (Ost 1992). It has been suggested that an inherited overactive baroreflex may contribute to the high rate of familial transmission of blood phobias (Adler et al. 1991).

**Neurobiological Factors**

In contrast to the situation with other anxiety disorders, little is known about the physiological correlates of specific and social phobias. Only a few studies have examined physiological correlates of specific phobia. Research examining brain activity during the experience of phobic fear using positron emission tomography has yielded inconsistent results (Rauch et al. 1995, Wik et al. 1997), with some studies finding changes in cerebral blood flow associated with viewing phobia-relevant scenes and some studies finding no differences in cerebral blood flow between participants with and without phobias. In social phobia, decreased regional cerebral blood flow response to an anxiogenic public speaking task has been found bilaterally in the amygdala, hippocampus, and the periamygdaloid, rhinal, and parahippocampal cortices in individuals treated with citalopram or cognitive–behavioral group therapy, but not in those assigned to a waiting list control (Fürmark et al. 2002). In addition, the degree of amygdalar–limbic attenuation was associated with clinical improvement in 1-year follow-up. Specific phobia may have been of less interest to researchers because no effective pharmacological treatments exist for this disorder. However, effective drug treatments have been identified for social phobia, leading to an increased interest in the biological factors underlying this disorder (Mathew et al. 2001).

Studies on the relationship between serotonin and social phobia have been mixed. Selective serotonin reuptake inhibitors (SSRIs) have been shown to be very effective in the treatment of social phobia. In addition, there is evidence of augmented cortisol response to fenfluramine in patients with social phobia, suggesting an association between social phobia and selective supersensitivity in the serotonergic system (Tancer et al. 1994, 1995). However,
there is research showing that [3H] paroxetine binding (an indicator of serotonergic functioning) does not differ between social phobia patients and nonanxious controls (Stein et al. 1995).

There has also been some evidence to suggest a relationship between dopamine and social phobia. Unlike panic disorder, which responds well to a variety of tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs) (e.g., Schweizer et al. 1993), social phobia tends to have a positive response to MAOIs and show little response to tricyclic antidepressants (Levin et al. 1989). Whereas tricyclic antidepressants tend to act on noradrenergic and serotonergic systems, MAOIs affect noradrenergic, serotonergic, and dopaminergic systems (Cooper et al. 1983). This finding has led some investigators to suggest that the dopamine system is primarily involved in social phobia (Levin et al. 1989), which would explain why biological challenges that appear to affect noradrenergic activity (e.g., sodium lactate infusion, carbon dioxide inhalation) have little effect on patients with social phobia, despite having panicogenic effects in patients with panic disorder (Rapee et al. 1992).

The dopamine hypothesis is consistent with findings that dopamine metabolize levels correlate with measures of extroversion (King et al. 1986) as well as findings that mice bred to be timid have been shown to be deficient in brain dopamine concentration (Lewis et al. 1989). In addition, a neuroimaging study found that striatal dopamine uptake site densities were significantly lower in patients with social phobia as compared to controls (Tiihonen et al. 1997).

With respect to neuroendocrine correlates in social phobia, studies of the hypothalamic–pituitary–thyroid and hypothalamic–pituitary–adrenal axes in social phobia have found few differences between patients with social phobia and control persons. For example, research has found that patients with social phobia and controls did not differ on tests of thyroid function (Tancer et al. 1990) or levels of urinary free cortisol (Potts et al. 1991). However, more recent studies have found evidence of cortisol differences associated with social anxiety. Some research has found that shy children have higher salivary cortisol than nonshy children (Schmidt et al. 1997), whereas other studies have found evidence of lower salivary cortisol in socially anxious undergraduate students than in non-anxious students (Beaton et al. 2006). In comparison to control volunteers, social phobia patients have also been found to show dichotomies in the distribution and magnitude of their cortisol response to a speech task (social phobia-related stress task), but not a physical exercise task (non-social phobia-related stress task) (Furlan et al. 2001).

Imaging studies have found a number of differences between social phobia patients and controls. One study using functional magnetic resonance imaging (fMRI) found that conditioned aversive stimuli were associated with increased activation in the amygdala and hippocampus of social phobia patients, whereas decreased activation in these areas was observed in normal controls (Schneider et al. 1999). Other research using repeat proton magnetic resonance spectroscopy has found significant differences between individuals with social phobia and controls in cortical gray matter. Specifically, Tupler et al. (1997) found that social phobia is associated with specific choline and myoinositol abnormalities in cortical and subcortical gray areas of the brain. Another study using single photon emission computer tomography (SPECT) found that after an 8-week trial of citalopram there was significantly decreased activity in the anterior and lateral part of the left temporal cortex, the left cingulum, and the anterior, lateral, and posterior part of the left midfrontal cortex in a small (N = 15) sample of social phobia patients (Van der Linden et al. 2000a). Compared to treatment responders, treatment nonresponders had higher activity at baseline in the lateral left temporal cortex and the lateral left midfrontal regions. Further research is necessary to understand the significance of these imaging findings as well as their specificity to social phobia.

A few studies have examined patterns of brain activity associated with shyness. In a study on high and low shyness (anxious self-preoccupation and avoidance of social situations) and sociability (preference to be socially active and seek out social situations) in college students, Schmidt (1999) found that shyness was associated with greater relative right frontal electroencephalogram (EEG) activity, whereas sociability was associated with greater relative left frontal EEG. In addition, Schmidt (1999) found the pattern of absolute EEG power in each frontal hemisphere differed for high shy/high social participants and high shy/low social participants.

Finally, there may be good reason to consider different underlying mechanisms in patients with performance-related phobias (e.g., public speaking) than those patients with generalized social phobia (i.e., those who fear most social situations). Individuals with performance-related phobias tend to show more autonomic reactivity (e.g., rapid heart beat) in the phobic situation than do patients with generalized social phobia (Levin et al. 1993). In addition, beta-blockers such as atenolol may be useful for decreasing performance anxiety in normal individuals (Gorman and Gorman 1987), although they have little effect on patients with generalized social phobia (Liebowitz et al. 1992). These facts have led some investigators to suggest that adrenergic hyperactivity may be involved in performance anxiety but not in generalized social phobia (Levin et al. 1989). However, it should be noted that despite limited evidence for the use of beta-blockers in normal groups (e.g., musicians with performance anxiety), their utility for treating patients with a diagnosis of social phobia (e.g., performance fears that lead to significant distress or impairment) has not been established.

Psychological and Social/Environmental Factors

Psychoanalytic Perspectives

Historically, the etiology of phobic disorders was typically explained from a psychoanalytic perspective. Freud postulated that phobias may often stem from an unresolved oedipal conflict. Specifically, incestuous sexual desire is proposed to lead to anxiety associated with being attacked and castrated. Although the defense mechanism of repression is typically used to protect the individual from experiencing the anxiety (and the underlying conflict), when repression is insufficient the ego must use additional defense mechanisms. In the case of individuals with phobias, Freud proposed that displacement of the anxiety to a less relevant object or situation occurs (such as a dog or some other animal),
so that the feared object is used to symbolize the primary source of the conflict. Patients with phobias use avoidance to further escape the effects of the anxiety (Nemiah and Uhde 1989). Although Freud’s theory was once influential, its impact on current thinking among researchers has waned. Rather, most current research on psychological factors in the development of phobias has tended to focus on conditioning and information-processing theories and their interaction with neurobiological processes and environmental factors.

Learning and Conditioning Perspectives

Emotions are “contagious.” That is, we learn to respond to stimuli, in part, by observing other people’s responses and also by our own experiences in these situations. In other words, we come to fear dangerous situations easily. This is important from an ethological perspective because our ancestors who could learn to fear threatening objects or situations easily were more likely to survive and pass these genes to their offspring. This inherited tendency to learn to experience fear in particular situations is the basis of conditioning models of phobia development.

Mowrer’s Two-Stage Model

The two-stage model of Mowrer (1939) was a precursor to current conditioning models for phobia development. According to Mowrer, the first stage in the development of fear involves a classical conditioning process by which a previously neutral stimulus is associated with an aversive stimulus so that the neutral stimulus becomes a trigger for fear. For example, a fear of dogs might develop after an individual is bitten (an aversive stimulus) by a dog (a neutral stimulus). Mowrer’s second stage relies on operant conditioning principles to explain the maintenance of phobias. According to Mowrer, phobias are maintained by negative reinforcement resulting from avoidance of the phobic object. In other words, avoidance prevents the uncomfortable symptoms that occur when one is frightened and thereby maintains the desire to avoid the phobic object and situation.

Despite the research interest generated by Mowrer’s model, the model suffers from several problems. First, many individuals report no specific conditioning experiences that trigger their phobias. In fact, many individuals report having fears despite never even having encountered the phobic situation, let alone having experienced a trauma in the phobic situation. Second, Mowrer’s theory does not explain why many individuals experience traumas but never develop fears. For example, one study found that although traumatic events were reported to be the cause of fear among 56% of individuals with fears of dogs, 66% of nonfearful subjects reported a history of traumatic experiences with dogs that did not lead to the development of fear (Di Nardo et al. 1988).

Rachman’s Pathways to Fear Development

In response to these and other concerns with Mowrer’s model, Rachman (1977) proposed three pathways to the development of fear. The first of these is direct conditioning, which typically involves the experience of being hurt or frightened by the phobic object or situation. Examples include being involved in an automobile accident, being humiliated in front of a group, falling or almost falling from a high place, or fainting at the sight of blood. Rachman’s second pathway is called vicarious acquisition, which involves witnessing some traumatic event or seeing someone behave fearfully in the presence of a phobic situation. For example, a child might develop a fear of snakes after seeing her father behave fearfully around snakes, or someone might develop a fear of public speaking after seeing another individual heckled by the audience during a presentation. For the third pathway, Rachman proposed that fears can develop through informational and instructional pathways, which refer to the processes of learning through information obtained verbally from other people, the media, or various other sources. It is not surprising that individuals might develop flying phobias, given the frequency with which plane crashes are reported in the news. Similarly, a child might develop a fear of heights if his parents frequently warned him of the dangers of being near high places.

In addition to these pathways, Rachman acknowledged the role of biological constraints on the development of fear. Of particular relevance is the fact that fears are not simply randomly distributed. To explain this observation, Seligman (1971) proposed that organisms are predisposed to learn certain associations and not others. Seligman called his theory “preparedness” and hypothesized that individuals are “prepared” to develop some associations that lead to fear and not others. For example, an individual might be more likely to develop a fear of snakes after being bitten than to develop a fear of flowers after being pricked by a thorn. Seligman proposed that these associations evolved through natural selection processes to facilitate survival.

Evidence for the theory of preparedness is mixed. Although some authors have concluded that the studies to date do not support preparedness (McNally 1987), it may be argued that these studies have not adequately tested the theory. Most studies examining preparedness have attempted to associate dangerous objects (e.g., snakes) and nondangerous objects (e.g., flowers) with an aversive electric shock and have found few differences in the subsequent development of fear. However, preparedness predicts that some “associations” are more difficult to establish than others, not that some “objects” are more easily feared than others. The theory does not necessarily predict that shock should be more easily associated with snakes than with flowers. A more appropriate experiment might be to compare the effects of a minor snakebite to the effects of being pricked by a thorny flower on the development of fear of each object.

Though the effects of preparedness have not been completely established, there remains strong evidence that conditioning processes can play an important role in the development of phobic disorders (Bouton et al. 2001). Numerous studies have examined the frequency with which Rachman’s three pathways lead to fear development, as illustrated in Table 70–4. Most of these studies have focused on the development of specific phobias, although a few studies included social phobia groups. The majority of studies have found support for the model, indicating that both direct and indirect forms of phobia acquisition occur frequently across a wide range of phobia types (e.g., Merckelbach and Muris 1997, Muris et al. 1997, Townend et al. 2000). However, numerous people report onsets that are unrelated to these pathways (e.g., “I have had this fear..."
for as long as I can remember” or “I have always had this fear”). Overall, it appears that direct and indirect methods of fear development are relatively common, although the frequency of these onsets varies greatly across studies for a variety of reasons. First, studies have been inconsistent with respect to the populations studied (e.g., clinical groups, nonclinical participants such as college students, individuals recruited through advertisements). In addition, some studies included mixed groups of patients who have a similar fear, but for very different reasons (e.g., flying fears can be due to a specific phobia of flying, claustrophobia, or agoraphobia). Third, studies differed in the ways in which each pathway was defined. For example, an onset that followed an unexpected panic attack was included among the traumatic onsets in some studies but not others. Finally, some studies allowed participants to list multiple causes, whereas other studies had participants rate only the primary cause.

In addition to methodological differences, the inconsistency across studies may be partly explained by the lack of reliability of retrospective self-report. More recent studies have examined onset of phobias in children and included parental interviews to avoid problems associated with retrospective report (Merckelbach and Muris 1997, Poulton et al. 1999).

Despite the high frequency of direct and indirect conditioning events and informational onsets, it appears that they are not the whole story. In fact, studies have begun to include normal comparison groups and have found that these events are equally common in individuals who do not have phobias (e.g., Hofmann et al. 1995a, Menzies and Parker 2001, Merckelbach et al. 1992). Ultimately, to answer the question of how phobias begin, we must discover the variables that lead only certain individuals to develop phobias after experiencing conditioning events or receiving information that leads to fear. For example, several investigators have found that a tendency to feel “disgust” in response to certain stimuli may be important in the development of some animal phobias and blood phobias (Sawchuk et al. 2000, Woody and Teachman 2000). In addition, heightened disgust sensitivity in parents has been found to predict fear of disgust-relevant animals (e.g., snakes, mice, slugs, and cockroaches) in children (de Jong et al. 1997).

Several other variables have also been suggested as mediating factors in the development of fear. Stress at the time of the event may make individuals more likely to react fearfully. In addition, previous and subsequent exposure to the phobic object may protect an individual from the development of some animal phobias and blood phobias (Sawchuk et al. 2000, Woody and Teachman 2000). In addition, heightened disgust sensitivity in parents has been found to predict fear of disgust-relevant animals (e.g., snakes, mice, slugs, and cockroaches) in children (de Jong et al. 1997).

personality factors may influence an individual’s likelihood of developing a phobia after a conditioning event. In fact, there is evidence that personality factors and parenting styles may be especially relevant to the development of social phobia. Familial environment including parental style (overprotective or rejecting), parental modeling, and degree of exposure to social situations are specific risk factors that have been associated with increased vulnerability for the development of social phobia (Wittchen and Fehm 2003).

It has been proposed that a fourth nonassociative pathway be added to Rachman’s three associative pathways to fear development (Poulton and Menzies 2002). Nonassociative fear models (Menzies and Clarke 1995) propose that a limited number of fears are not acquired by conditioning or other learning processes. Rather, these evolutionary adaptive fears are proposed to be innate or biologically determined. This is similar to preparedness theory, however, it maintains that fears are acquired through a learning or conditioning process and that some fears are more easily learned than others. According to Poulton and Menzies (2002), the nonassociative pathway to fear acquisition helps to explain a number of research findings that run counter to associative models of fear development including the nonrandom distribution of common fears, and the emergence of some fears without any prior specific associative learning experiences (i.e., direct conditioning, vicarious conditioning, or informational transmission).

Based on current evidence, Rapee and Spence (2004) proposed an etiological model of social phobia in an attempt to capture the complexity of the disorder. According to their model, individuals have a “set point” level of social anxiety that is somewhat stable and consistent, and is directed by broad genetic factors (e.g., general emotionality, sociability). This set point may become altered up or down in response to primarily environmental factors (e.g., parents, peers, negative life events, culture, interrupted social performance, poor social skill). These environmental events may exert a powerful influence due to timing (critical stage of vulnerability), impact (intensity or meaning of the event), or chronicity. For example, a significant proportion of individuals with social phobia report having been severely teased or bullied during childhood (McCabe et al. 2003).

**Personality Variables**

The work of Kagan and others (Kagan et al. 1984, Rosenbaum et al. 1991) has suggested that as early as 18 months of age, children differ with respect to their tendency to interact with other individuals, toys, and objects. Although about 70% of children are somewhat exploratory in these situations, about 15% of children are extremely exploratory, and the remaining 15% are quite shy and withdrawn. The behavior exhibited by the shy and withdrawn children has been called “behavioral inhibition” and has been proposed to be a predisposing factor in the development of social phobia and other anxiety disorders (Turner et al. 1996). One study found that the prevalence of social phobia was significantly greater (17%; N = 64) in children with behavioral inhibition than without (5%; N = 152) (Biederman et al. 2001). In addition, compared with nonanxious individuals, patients with social phobia describe their parents as having (1) discouraged them from socializing, (2) placed undue importance on the opinions of others, and (3) used shame as a means of discipline (Bruch and Heimberg 1994). Other predictors of the development of social phobia include a childhood history of separation anxiety, self-consciousness or shyness in childhood and adolescence, and a low frequency of dating in adolescence (Bruch 1989, Bruch and Heimberg 1994).

Perfectionism is another personality variable that has been associated with social phobia (Antony et al. 1998a). Although several other anxiety disorders have also been associated with perfectionism, concern about making mistakes and a perception of having critical parents are highest among individuals with social phobia compared to individuals with other anxiety disorders (e.g., panic disorder, obsessive-compulsive disorder, or specific phobia).

**Cognitive Variables**

Numerous studies have examined the role of cognitive variables in social and specific phobias and have consistently found that individuals with these disorders exhibit attentional and attributional biases regarding the phobic object or situation. In studies of information processing, people with social and specific phobias devote more attention to threat-related information than do nonphobic individuals (Kindt and Brosschot 1999, Mattia et al. 1993). They also show perceptual and cognitive distortions consistent with their phobias (Jones and Menzies 2000, Pauli et al. 1998, Purdon et al. 2001, Rapee 1997, Roth et al. 2001). For example, individuals with snake or spider phobias tend to overestimate the degree of activity in the feared animal before treatment but not after treatment (Rachman and Cuk 1992). Likewise, people with social phobia tend to rate their own performance during public speaking more critically than do nonphobic control subjects (Rapee and Lim 1992). Furthermore, the discrepancy between self-ratings and observer ratings is greater for people with social phobia than control subjects (Norton and Hope 2001). In addition, individuals with social phobia tend to report more negative self-evaluative thoughts and underestimate their performance when interacting with others relative to nonanxious subjects (Stopa and Clark 1993). More recent research has found that compared to nonanxious individuals, individuals with social phobia are more likely to experience negative imagery and to take an observer’s point of view (i.e., see themselves from an external perspective) when exposed to feared social situations (Hackmann et al. 1998, Wells and Papageorgiou 1999). Other research has found that social phobia is associated with impaired thought suppression affecting both social phobia-related stimuli as well as nonsocial phobia-related stimuli (Fehm and Margraf 2002).

Although it is clear that cognitive biases exist in individuals with phobias and that attentional and attributional biases improve after effective treatment, it is not known whether the cognitive biases exhibited by patients contribute to the development of the fear or whether they are simply a manifestation of the fear. However, there is evidence that symptomatic improvement in social phobia is associated with reductions in interpretive biases and self-focused attention (for review, see Clark and McManus 2002).

**Treatment**

Following a discussion of treatment goals, this next section provides an empirical review of somatic and psychosocial treatments for social phobia and specific phobia. Effective
treatments fall into two main categories: pharmacological treatment and cognitive behavioral treatment (CBT). Pharmacological treatments have been used effectively for treating social phobia, although it is generally accepted that they are of limited utility for treating specific phobias. In contrast, CBT has been used with success for the treatment of specific and social phobias. Despite the existence of effective treatments, fewer than half of those who seek treatment in an anxiety disorders specialty clinic have previously received evidence-based treatments for their social anxiety (Rowa et al. 2000). Tables 70–5 and 70–6 summarize various treatments for social and specific phobias. See Swinson et al. (2006) for a comprehensive review of treatment guidelines for social and specific phobias, as well as other anxiety disorders.

**Treatment Goals**

The main goal of treatment is to decrease fear and phobic avoidance to a level that no longer causes significant distress or functional impairment. In some cases, treatment includes strategies for improving specific skill deficits as well. For example, individuals with social phobia may lack adequate social skills and can sometimes benefit from social skills training. Likewise, some individuals with specific phobias of driving may have poor driving skills if their fear has prevented them from learning how to drive properly. Typically, effective treatment for social phobia lasts several months, although treatment of discrete social phobias (e.g., public speaking) may take less time. Specific phobias can usually be treated relatively quickly. In fact, for certain phobias (e.g., animals, blood, injections), the vast majority of individuals are able to achieve clinically significant, long-lasting improvement in as little as one session of behavioral treatment (Öst et al. 2001).

**Somatic Treatments**

### Specific Phobia

As discussed earlier, pharmacotherapy is generally thought to be ineffective for specific phobias. However, little research has been conducted to assess the utility of medications for

+++ First treatment of choice. Helpful for most patients, with few side effects. Good long-term benefits.

+++ Helpful for most patients. Potential for relapse after treatment is discontinued.

++ Second-line or third-line treatment due to a need for additional research, mixed evidence, or other issues (e.g., significant side effects).

+ Not especially effective for generalized social phobia.
specific phobias, and it is not uncommon for phobic patients occasionally to be prescribed low dosages of benzodiazepines to be taken in the phobic situation (e.g., while flying). The few relevant studies that have been conducted have examined the use of benzodiazepines and beta-blockers alone or in combination with behavioral treatments for specific phobias and in general have found that drugs do not contribute much to the treatment of specific phobias (Antony and Barlow 2002). However, one problem with the research to date is that it has not taken into account differences among specific phobia types. For example, claustrophobia and other phobias of the situational type appear to share more features with panic disorder than with the other specific phobia types (Antony et al. 1997a). Therefore, medications that are effective for panic disorder (e.g., imipramine, alprazolam) may prove to be effective for situational phobias. Although there are few studies examining this hypothesis, preliminary data suggest that benzodiazepines may be helpful in the short-term but lead to greater relapse in the long-term and possibly interfere with the therapeutic effects of exposure across sessions (Wilhelm and Roth 1996). For example, one study found that CBT and benzodiazepines both led to fear reduction during dental surgery; however, whereas benzodiazepine treatment was associated with greater relapse during follow-up, CBT was associated with further improvements (Thom et al. 2000).

There have been very few controlled studies to date examining the effectiveness of antidepressants for specific phobia. One placebo-controlled, double-blind pilot study found that paroxetine was superior to placebo in reducing anxiety and fear levels in individuals with different types of specific phobia (Benjamin et al. 2000). There have also been several case study reports indicating the usefulness of selective serotonin reuptake inhibitors in the treatment of specific phobia. For example, one single-case study found fluvoxamine to be effective in the treatment of a specific phobia of storms in an 11-year-old boy who also had depression, school phobia, and obsessive–compulsive symptoms (Balon 1999). Another single-case study found that fluoxetine led to a reduction in flying phobia in two patients being treated for depression (Abene and Hamilton 1998).

**Social Phobia**

In contrast to specific phobias, social phobia has been treated successfully with a variety of pharmacological interventions including SSRIs such as sertraline (Blomhoff et al. 2001, Van Ameringen et al. 2001), fluvoxamine (Stein et al. 1999, van Vliet et al.), fluvoxamine CR (Stein et al. 2003), fluoxetine (Davidson et al. 2004), citalopram (Furmark et al. 2002), escitalopram (Kasper et al. 2005), and paroxetine (Allgounder and Nilsson 2001, Liebowitz et al. 2002, Stein et al. 1999b), benzodiazepines such as clonazepam (Davidson et al. 1993) and alprazolam (Reich and Yates 1988), traditional monoamine oxidase inhibitors (MAOIs) such as phenelzine (Heimberg et al. 1998), serotonin norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine (Liebowitz et al. 2005), and reversible inhibitors of monoamine oxidase A (RIMA) such as moclobemide (Versiani et al. 1996) and brofaromine (Lott et al. 1997).

Numerous controlled trials across a range of SSRIs including sertraline, fluvoxamine, and paroxetine have demonstrated their efficacy in the treatment of social

phobia, such that the SSRIs are currently considered the first-line medication treatment (for a meta-analysis of randomized controlled trials, see Van der Linden et al. 2000b). Preliminary research indicates that paroxetine may be useful in the treatment of individuals with comorbid social phobia and alcohol use disorder (Randall et al. 2001). Due to their tolerability and efficacy, the SSRIs have been referred to as “the new gold standard” in pharmacological treatment for social phobia (Van Ameringen et al. 1999, 2000). Another benefit of SSRIs is their broad spectrum efficacy for common comorbid disorders such as depression and panic disorder. Interestingly, despite the evidence for SSRIs as a first-line treatment for social phobia, examination of prescribing practices over a 12-year period in 232 patients with social phobia reflect that benzodiazepines continue to be more commonly prescribed over SSRIs and use of SSRIs as stand-alone medication remains low (Vasile et al. 2005).

Research on the use of anxiolytics for the treatment of social phobia has focused on high potency benzodiazepines (e.g., clonazepam, alprazolam) and the nonbenzodiazepine buspirone. Several studies have examined the utility of clonazepam for treating social phobia. In a placebo-controlled study, Davidson et al. (1993) found that 78% of patients responded to clonazepam (mean dosage, 2.4 mg/day), whereas only 20% responded to placebo. One study comparing clonazepam to cognitive-behavioral group therapy found that patients in both conditions improved significantly and no differences between treatment conditions were observed aside from greater improvement in the clonazepam group at 12 weeks of treatment (Otto et al. 2000). These results confirmed findings from smaller open trials and case studies supporting the use of clonazepam for social phobia (mean dosages, 2.1–2.75 mg/day) (Davidson et al. 1991a, Munjack et al. 1990). In addition, uncontrolled pilot studies have suggested that alprazolam (mean dosage, 2.9 mg/day) (Lydiard et al. 1988, Reich and Yates 1988) may be effective for social phobia, although more controlled clinical trials are needed. The findings from controlled trials on buspirone have found no significant advantage of buspirone over placebo (Clark and Agras 1991, van Vliet et al. 1997), though previous uncontrolled studies had found some benefit following treatment with buspirone (Munjack et al. 1991, Schneier et al. 1993).

Due to the potentially severe side effects of MAOIs as well as the necessity for certain dietary restrictions, they are not recommended as a first-line treatment. The findings from more recent trials involving RIMAs have been less encouraging than those from earlier studies. For example, a fixed dose study conducted over 12 weeks found that moclobemide did not have a significant benefit over placebo at five dosages ranging from 75 to 900 mg/day (Noyes et al. 1997). Other studies have also found poor responses to moclobemide (Oosterbaan et al. 2001, Schneier et al. 1998). Discontinuation of MAOIs and RIMAs has been associated with a tendency to relapse.

Research on beta-blockers indicates that they are no better than placebo for most patients with generalized social phobia (Liebowitz et al. 1992). Although beta-blockers have been used to treat individuals from nonpatient samples with heightened performance anxiety (e.g., people with public speaking anxiety, musicians with stage fright) (Hartley et al. 1983), their efficacy for treating individuals with clinically diagnosed discrete social phobia has not been established. Nevertheless, beta-blockers are often prescribed for discrete performance-related social phobias.

Preliminary findings suggest that medications such as gabapentin and pregabalin, typically used in the treatment of partial seizures, may be effective in the treatment of social phobia. Placebo-controlled trials have found that patients taking gabapentin and pregabalin had significant reductions in social anxiety compared to patients in the placebo groups (Pande et al. 1999, 2004). However, further research is needed to confirm these findings.

**Psychosocial Treatments**

### Specific Phobias

Numerous studies have shown that exposure-based treatments are effective for helping patients to overcome a variety of specific phobias including fears of blood (Öst et al. 1991), injections (Öst 1989), dentists (Moore and Brodsgaard 1994), spiders (Muris et al. 1998, Öst 1996a), snakes (Gauthier and Marshall 1977), rats (Foà et al. 1977), enclosed places (Craske et al. 1995), thunder and lightning (Öst 1978), water (Menzies and Clarke 1993a), flying (Öst et al. 1997), heights (Baker et al. 1973), choking (McNally 1986), and balloons (Houlihan et al. 1993).

The way in which exposure is conducted appears to make a difference. Exposure-based treatments can vary on a variety of dimensions including the degree of therapist involvement, duration and intensity of exposure, frequency and number of sessions, and the degree to which the feared situation is confronted in imagination versus in real life. In addition, because individuals with certain specific phobias often report a fear of panicking in the feared situation, some investigators (Antony and Swinson 2000a) have suggested that adding various panic management strategies (e.g., cognitive restructuring, exposure to feared sensations) may help to increase the efficacy of behavioral treatments for certain specific phobias. It remains to be shown whether the addition of these strategies will improve upon the efficacy of treatments that include only exposure.

Several reviews have summarized the effects of the above mentioned variables on exposure-based treatments (Antony and Barlow 2002, Antony and Swinson 2000a). Although some studies have led to contradictory results, the following generalizations are more or less accepted by the majority of investigators. First, exposure seems to work best when sessions are spaced close together. Second, prolonged exposure seems to be more effective than exposure of shorter duration. Third, during exposure sessions, patients should be discouraged from engaging in subtle avoidance strategies (e.g., distraction) and overreliance on safety signals (e.g., being accompanied by one’s spouse during exposure). Fourth, real-life exposure is more effective than exposure in imagination. Fifth, exposure with some degree of therapist involvement seems to be more effective than exposure that is exclusively conducted without the therapist present (Park et al. 2001). Exposure may be conducted gradually or quickly. Both approaches seem to work equally well, although patients may be more compliant with a gradual approach. Finally, in the case of blood and injection phobias, the technique called applied muscle tension (Öst and Sterner...
approaches to be equivalent (e.g., Emmelkamp et al. 2002, Dewis et al. 2001) whereas other studies have found the two to be more efficacious than wait-list control for height fears (Vu et al. 2001). The evidence suggests that the addition of cognitive strategies to exposure may provide added benefit (Craske et al. 1995) for some individuals. For a detailed guide to integrating cognitive strategies with exposure see Antony and Swinson (2000a).

Specific phobias are among the most treatable of the anxiety disorders. For example, in as little as one session of guided exposure lasting 2–3 hours, the majority of individuals with animal or injection phobias are judged much improved or completely recovered (Antony et al. 2001a; Öst 1989; Öst et al. 1997). One study demonstrated that one session of exposure treatment was effective in the treatment of children and adolescents with various specific phobias (Öst et al. 2001). Moreover, exposure conducted with a parent present was equally effective as exposure treatment conducted alone (Öst et al. 2001). However, despite how straightforward the concept of exposure may seem, many subtle clinical issues can lead to problems in implementing exposure-based treatments. For example, although a patient might be compliant with therapist-assisted exposure practices, he or she may refuse to attempt exposure practices alone between sessions. In such cases, involving a spouse or other family member as a coach during practices at home may help. In addition, gradually increasing the distance between therapist and patient during the therapist-assisted exposures will help the patient to feel comfortable when practicing alone. However, to maintain the patient’s trust and to maximize the effectiveness of behavioral interventions, it is important that exposure practices proceed in a predictable way, so that the patient is not surprised by unexpected events. Several self-help books and manuals for treating a range of specific phobias have been published in the past decade. Whereas some of these manuals were developed to be used with the assistance of a therapist (Antony et al. 2006; Craske et al. 2006), others were developed for self-administration (Antony and McCabe 2005, Antony and Rowa 2007, Antony and Watling 2006).

Recent developments in technology have started to have an impact on the treatment of specific phobias. Videotapes are commonly used to show feared stimuli to patients during exposure. Computer assisted or assisted behavioral treatments such as computer-guided self-exposure have also been used (Marks et al. 2004; Smith et al. 1997). More recent is the use of virtual reality to expose patients to simulated situations that are more difficult to replicate in vivo such as flying (Kahan et al. 2000) and heights (Rothbaum et al. 1995) as shown in Figure 70–3. Emerging data on the effectiveness of virtual reality is encouraging (Rothbaum et al. 2000). Controlled studies have found virtual reality treatment to be more efficacious than wait-list control for height fears (Krijn et al. 2004) and fear of flying (Rothbaum et al. 2000). Some studies suggest that in vivo exposure is still superior (Dewis et al. 2001) whereas other studies have found the two approaches to be equivalent (e.g., Emmelkamp et al. 2002, Rothbaum et al. 2002).

Social Phobia

Empirically validated psychosocial interventions for social phobia have primarily come from a cognitive–behavioral perspective and include four main types of treatment: (1) exposure-based strategies, (2) cognitive therapy, (3) social skills training, and (4) applied relaxation (Antony and Swinson 2000a, Turk et al. 1999). Exposure-based treatments involve repeatedly approaching fear-provoking situations until they no longer elicit fear. Through repeated exposure, patients learn that their fearful predictions do not come true despite their having confronted the situation. Table 70–7 illustrates an example of an exposure hierarchy that might be used to structure a patient’s exposure practices. An exposure hierarchy is a list of feared situations that are rank ordered by difficulty and used to guide exposure practices for phobic disorders including social phobia and specific phobia. The patient and therapist generate a list of situations that the patient finds anxiety provoking. Items are placed in descending order from most anxiety provoking to least anxiety provoking, and each item is rated with respect to how anxious the patient might be to practice the item. Exposure practices are designed to help the patient become more comfortable engaging in the activities from the hierarchy. Cognitive therapy helps patients identify and change anxious thoughts (e.g., “Others will think I am stupid if I participate in a conversation at work”) by teaching them to consider alternative ways of interpreting situations and to examine the evidence for their anxious beliefs. Social skills training is designed to help patients to become more socially competent when they interact with others. Treatment strategies may include modeling, behavioral rehearsal, corrective feedback, social reinforcement, and homework assignments. Finally, applied relaxation has been studied primarily by Öst et al. (1984) and involves learning to relax one’s muscles during rest, during movement, and eventually in anxiety-provoking social situations.

Although these methods are presented as four distinct treatment approaches, there is often overlap among the various treatments. Social skills training typically requires exposure to the phobic situation so that new skills may be practiced (e.g., behavioral rehearsal). The same may be said of applied relaxation, which includes learning to conduct relaxation exercises in the phobic situation. In fact, most treatments for social phobia involve some type of exposure to anxiety-provoking social interactions and performance-related tasks. Furthermore, many cognitive–behavioral therapists treat patients using several different strategies delivered in a comprehensive package.

Studies demonstrating the efficacy of CBT for social phobia are too numerous to describe in detail, although several representative studies are reviewed here. In addition, studies that specifically compare cognitive–behavioral and medication treatments are described. For interested readers, more comprehensive reviews on CBT for social phobia have been written by Rowa and Antony (2005) and Fresco and Heimberg (2001). Also, a clinical description of a cognitive–behavioral group treatment (CBGT) for social phobia is provided by Turk et al. (2001) and by Heimberg and Becker (2002).

Several studies have compared various cognitive–behavioral strategies and their combinations for treating social phobia. For example, Wlazlo et al. (1990) compared...
those individuals with deficits to develop their skills through exposure to social situations and interactions in the group. Mattick and Peters (1988) found that guided exposure was more effective when cognitive therapy was included than when exposure was conducted without cognitive therapy. Scholing and Emmelkamp (1993) failed to replicate this finding and found that treatment was equally effective when exposure was conducted alone, it followed several sessions of cognitive therapy, or was integrated with cognitive therapy from the first session.

Whereas these studies examined the use of specific cognitive–behavioral strategies, other studies have examined the use of comprehensive treatments that include several therapeutic components. For example, Turner et al. (1994) evaluated their multicomponent social phobia treatment that included education, social skills training, exposure, and programmed practice between sessions. All patients had the generalized subtype of social phobia and were judged to be severely disabled by their symptoms. On a comprehensive measure of end-state functioning, 85% of patients met moderate to high end-state functioning criteria by the end of treatment. Unfortunately, this study did not include a comparison treatment group.

Heimberg et al. (1990b) compared supportive psychotherapy with a comprehensive CBGT package that social skills training to exposure therapy conducted either individually or in groups. All three treatments led to significant improvements and there were no differences between treatments. However, exposure therapy conducted in groups tended to be more effective for the subset of patients with social skills deficits, most likely by enabling

Figure 70–3 Virtual reality exposure is an emerging treatment for specific phobias related to situations that are difficult to replicate in vivo such as flying.
therapy was significantly better than both moclobemide and treatment. After a 2-month follow-up period, cognitive than moclobemide, but not placebo, after 15 weeks of active therapy to moclobemide for social phobia, Oosterbaan et al. (2001) found that cognitive therapy was significantly better immediately after treatment and at 3- and 6-month follow-up. CBGT was more effective despite the fact that patient ratings of treatment credibility and expectations for improvement were equal for both treatments. Patients receiving CBGT continued to be more improved at 5-year follow-up (Heimberg et al. 1993b), although only 41% of the original sample participated in the follow-up study, which limited the validity of these findings. Other research has confirmed that cognitive–behavioral therapy is superior to supportive therapy (Cottraux et al. 2000).

Heimberg et al. (1998) compared four treatments for social phobia: (1) CBGT, (2) phenelzine, (3) supportive psychotherapy, and (4) placebo. Overall, both phenelzine and CBGT were equally effective after 12 weeks of treatment and were significantly more effective than placebo or supportive psychotherapy. Phenelzine tended to work more quickly than CBGT and appeared to be more effective on a few measures. However, preliminary analyses of long-term outcome showed that after discontinuing treatment, patients receiving CBGT were more likely than patients who received phenelzine to maintain their gains, with approximately half of patients taking phenelzine relapsing, compared to none of the patients that responded to CBGT (Liebowitz et al. 1999).

In a randomized clinical trial comparing cognitive therapy to moclobemide for social phobia, Oosterbaan et al. (2001) found that cognitive therapy was significantly better than moclobemide, but not placebo, after 15 weeks of active treatment. After a 2-month follow-up period, cognitive therapy was significantly better than both moclobemide and placebo. In addition, treatment gains in the cognitive therapy group were maintained over a 15-month follow-up period.

A study by Haug et al. (2000) examined the effect of exposure therapy alone or in combination with sertraline for generalized social phobia in a primary care setting. Family physicians were trained for 30 hours in assessment of social phobia and in the application of exposure therapy. Family physicians reported satisfaction with the training program and found that the exposure treatment was also useful for treating patients with other conditions. Although exposure therapy and sertraline were effective alone, the combination of exposure therapy and sertraline appeared to confer added benefit.

In the most comprehensive study to date examining the relative and combined effects of CBT and medication, Davidson et al. (2004) compared CBT alone to fluoxetine alone, placebo, CBT plus fluoxetine, and CBT plus placebo. By the end of treatment, all four active treatments were more effective than placebo, and there were no differences between them. In this study, combined treatment was no more effective than either medication or CBT alone.

According to cognitive models of social phobia, one of the mechanisms by which CBT works is by causing a positive shift in an individual’s self-representation (e.g., decreased negative self-focused thoughts and increased task-focused thoughts and positive self-focused thoughts). Indeed, there is evidence that following CBT, individuals report significantly fewer negative self-focused thoughts (Hofmann 2000). Similarly, cognitive biases are reduced following successful pharmacotherapy treatment as well and are related to the degree of symptomatic improvement in both psychological and pharmacological treatments (McManus et al. 2000).

In summary, it seems clear that effective psychosocial treatments and medications for social phobia exist. Although both types of treatments appear to be equally effective, each has advantages and disadvantages. Medication treatments may work more quickly and are less time-consuming for the patient and therapist. In contrast, improvement after CBT appears to last longer. Due to medication side effects, CBT may be more appropriate for some individuals. More studies are needed to examine the efficacy of combined medication and psychosocial treatments for social phobia. A meta-analysis of 24 studies examining cognitive–behavioral and medication treatments for social phobia found that both treatments were more effective than control conditions (Gould et al. 1997). In this study, the SSRIs and benzodiazepines tended to have the largest effect sizes among medications and treatments involving exposure either alone or with cognitive therapy had the largest effect sizes among CBT. Another meta-analytic study of 108 psychological and pharmacological treatment–outcome trials found that the pharmacotherapies (SSRIs, benzodiazepines, MAO inhibitors) were the most consistently effective treatments, with both SSRIs and benzodiazepine treatments equally effective and more effective than control groups (Fedoroff and Taylor 2001). Further, maintenance of treatment gains for CBT was moderate and continued during follow-up intervals. In comparison, it is not known the extent to which treatment gains for medication treatments are maintained following discontinuation. Reviews of the efficacy of pharmacological and cognitive–behavioral treatments suggest that successful treatments may involve medication, CBT, or a combination of both (Scott and Heimberg 2000). Detailed descriptions of cognitive–behavioral therapy for social phobia are available in a self-help format (e.g., Antony and Swinson 2000b). Self-help manuals may be used on their own or in conjunction with therapy.

Treatment decision trees for social and specific phobias are presented in Figures 70–4 and 70–5.

### Treatment Refractory Patients

Several variables may lead to an initially poor treatment response. Anticipating potential difficulties will help increase treatment efficacy. Possible reasons for a worse outcome include poor compliance, poor motivation, and poor understanding of the treatment procedures. In addition, interpersonal issues and other possible conflicts may interfere with the successful treatment of specific and social phobias.

Patients fail to comply with treatment procedures for a variety of reasons. In the case of pharmacological treatments, patients may avoid taking medications because of side effects, lack of confidence in efficacy, or preference for an alternative type of treatment. If patients are not compliant with medications, the physician should attempt to identify the reasons for poor compliance and to suggest methods of increasing compliance or changing to another type of treatment.

In the case of CBT, common reasons for poor compliance are anxiety about the treatment procedures, lack of time, and lack of motivation to conduct the treatment.

**Figure 70–5 Specific phobia: treatment decision tree.**
properly. Because CBT requires patients to confront the situations they fear most, patients often feel extreme anxiety about participating in the treatment. Patients should be reassured that their anxiety is normal and that they will never be forced to do anything that they are unwilling to try. Furthermore, the difficulty of exposure tasks should be increased gradually to maximize treatment compliance. If patients do not have the time or motivation to conduct treatment as suggested, therapists should be willing to find ways to make the treatment more accessible to the patient. For example, involvement of a friend or relative of the patient as a coach may allow the patient to conduct more practices without the therapist’s assistance. The therapist could also explore the possibility that the patient consider beginning treatment later, when more time is available.

Poor motivation can lead to poor compliance with the treatment procedures. If a patient’s symptoms are not especially severe, the distress and impairment created by the disorder may not be enough to motivate the patient to take medications regularly or to confront the phobic situation in a systematic way. Furthermore, as a patient improves in treatment, she or he may experience a decrease in motivation. Patients should be encouraged to continue with treatment assignments even after improvement. More complete improvements may protect against a return of symptoms.

Finally, treatment procedures may be complicated for some patients. This is especially the case for CBT. Patients may fail to complete homework assignments (e.g., monitoring anxious cognitions) simply because the treatment rationale and the specifics of how to conduct the treatment procedures were not made clear. Therefore, therapists should continually assess the patient’s understanding of the treatment procedures.

**Special Factors Influencing Treatment**

**Predictors of Treatment Outcome**

A number of studies have examined predictors of outcome for treatment of specific and social phobias. These studies tend to fall into two main categories. First, several investigators have attempted to match treatment strategies to specific characteristics of patients. Second, several studies have examined the relationship between individual differences (e.g., duration and severity of illness, personality factors) and response to treatment.

Ost and colleagues conducted a series of studies to investigate whether specific types of individuals might benefit from particular types of treatment. For example, Ost et al. (1982) identified a group of individuals with claustrophobia who were primarily *behavioral responders* (i.e., for whom avoidance was the principal mode of responding) and another who were primarily *physiological responders* (i.e., for whom the principal response was increased arousal in the phobic situation). In this study, behavioral responders benefited more from exposure than from applied relaxation, whereas physiological responders benefited most from applied relaxation. Similar findings were found for behavioral and physiological responders with social phobia (Ost et al. 1981). However, despite small differences in treatment efficacy for different types of patients, the majority of patients seem to do well with either type of behavioral treatment.

Furthermore, many patients do not fall neatly into one category of responders but rather show features of both avoidance and physiological responding. Finally, several studies have failed to show differences in treatment efficacy for individuals with dental phobia (Jerremalm et al. 1986) and social phobia (Mersch et al. 1989) who have different response styles, which raises questions about the reliability of previous findings.

Heimberg and Juster (1995) reviewed some other predictors of response to CBT for social phobia. Subtype of social phobia seems to predict outcome (with generalized social phobia being associated with a worse treatment outcome than nongeneralized social phobia), but not when severity of symptoms is controlled. In other words, individuals with more severe symptoms before treatment can be expected to have more severe symptoms after treatment. With respect to comorbidity on outcome, findings have been mixed. Some research has found that the presence of comorbidity (additional personality, mood, or anxiety disorders) did not affect outcome following CBT for social phobia (Brown et al. 1995, Hofmann et al. 1995b, Van Velzen et al. 1997). However, other research has found that the presence of depression and avoidant personality traits were associated with a poorer outcome (Chambless et al. 1997, Scholing and Emmelkamp 1999).

Most pharmacological studies have failed to examine predictors of outcome. One exception was a study by Van Ameringen et al. (1993), who found that a shorter duration of symptoms and older age at onset were associated with more positive outcomes after treatment of social phobia with fluoxetine.

Several studies have examined characteristics of individual subjects that predict outcome in the behavioral treatment of specific phobias. Two studies have found that coping style predicts outcome. In one study, “monitors” (those who cope with fear by seeking fear-relevant information, e.g., scanning a room for spiders in the case of an individual with spider phobia) responded more poorly to behavioral treatment and relapsed more often compared with “blunters” (those who cope with fear by avoiding fear-relevant information, e.g., avoiding looking around for spiders for fear of seeing them) (Muris et al. 1993). However, another study led to opposite findings, with monitors responding most (Steketee et al. 1989). Finally, a study by Antony et al. (2001a) found no relationship between coping style and treatment outcome in a group of patients with spider phobia.

Other patient-related variables that may be associated with treatment outcome for specific phobias include symptom severity, level of generalized anxiety, previous experience with the phobic stimulus, and reliance on safety behavior during exposure. Specifically, patients with more severe height phobias have been shown to demonstrate greater change after treatment than did patients with less severe phobias (Baker et al. 1973), although that does not imply that their posttreatment symptoms are less severe. In addition, elevated generalized anxiety has been shown to be associated with poorer outcome in patients with height phobia (Baker et al. 1973). Moreover, extensive prior experience with flying has been shown to be associated with a worse outcome after behavioral treatment for flying phobia (Solyom et al. 1973). Allowing individuals to engage
Relapse and Return of Fear

With respect to specific phobia, it is common for some return of fear to occur in the presence of the phobic stimulus (Craske 1999). Although relapse following treatment of a specific phobia is believed to be rare (Öst 1996b), one study found a considerable proportion of individuals experienced a clinically significant return of symptoms over an average 12-year follow-up period (Lipsitz et al. 1999). A number of variables have been identified that predict return of fear including distraction during exposure, a relatively quick reduction in fear during exposure (Rose and McGlynn 1997), a relatively slow reduction in fear during exposure (Rachman and Whittal 1989), higher initial heart rate (Craske and Rachman 1987), spacing of exposure sessions and the degree to which the exposure stimuli are varied (Rowe and Craske 1998a, 1998b), the tendency to overassociate fear-relevant stimuli with aversive outcomes (de Jong et al. 1995), and depression (Salkovskis and Mills 1994). In addition, being challenged by the phobic stimulus in a context that is different from the context in which treatment took place may also increase the likelihood that fear will return (Mineka et al. 1999).

Clinical Vignette 1 • Social Phobia

Ms. K is a 29-year-old student who presented with social phobia. She reported being shy as a child and could remember pretending to be ill to stay home from school. As she got older, she met more children and by high school was quite comfortable with her friends at school. Meeting new people was still difficult, as was public speaking in class. Fortunately, neither situation came up often.

In college, Ms. K’s problem became worse. Several of her classes required her to make presentations. In addition, because she lived off campus, she found it particularly difficult to meet friends. The few times she tried to talk to people in class, she felt as though she had nothing to say. Before long, she stopped trying. Ms. K did not avoid her class presentations at first. Rather, she tended to overprepare for them and tried to use overheads when possible because the dark room helped to decrease her anxiety. Still during presentations she could feel her heart pounding and she tended to have difficulty breathing. Her mouth became dry and she was sure that her classmates could see her shaking and perspiring.

After her first year of college, Ms. K began to avoid any class that required presentations. In addition, she found herself avoiding other situations in which people might notice her shaking. Specifically, she avoided writing in front of others, holding drinking glasses, and other situations that might focus other people’s attention on her hands. She also avoided engaging in conversation with others and when people approached her, she tried to end the conversation as quickly as possible. In addition to fearing that others would notice her anxiety, Ms. K felt that others might see her as weak, unattractive, or foolish.

During a diagnostic interview, it was found that Ms. K was suffering from social phobia. She seemed bright and motivated, and it was decided that she might benefit from CBGT for social phobia. However, the patient initially rejected this option because of anxiety about participating in a group. Therefore, she started 10 mg of paroxetine and gradually increased the dosage to 50 mg. Because of difficulties due to sexual dysfunction, the dosage was decreased to 40 mg and her sexual symptoms subsided.

During a period of 6 weeks, Ms. K felt more comfortable around people and decided that she was willing to participate in a 12-session CBGT program. Treatment included a variety of components, including information about the nature of anxiety and social phobia, cognitive restructuring, role-play exposures to anxiety-provoking situations (e.g., group presentations), and homework assignments to enter feared situations. In addition, Ms. K practiced purposely shaking in front of others, until the symptom was no longer frightening to her. Over the course of the CBGT, Ms. K’s medication was gradually discontinued.

By the end of treatment, Ms. K was essentially symptom free and criteria for social phobia were no longer met. Furthermore, she had met several new friends and had enrolled in a few classes that required her to make presentations. Although she still became nervous before speaking in public, she looked forward to the presentations. She rarely experienced shaking in front of others and was no longer particularly concerned about shaking.

Clinical Vignette 2 • Specific Phobia

Mr. D, a 38-year-old attorney, presented for treatment of snake phobia. Growing up in New York City he rarely saw snakes, although he reported fearing toy snakes even as a child. In his late twenties, he relocated to a rural area where he encountered snakes every few weeks. Mr. D began to avoid entering his backyard and walking in his neighborhood, even with his family. Before he drove to work his wife checked the area around his car for snakes. His fear became worse over time so that even seeing a photograph of a snake induced a panic attack.

When Mr. D did see a snake he tended to have an intense panic attack, including breathlessness, dizziness, palpitations, and a feeling that he might lose control and embarrass himself. He was not sure how the fear...
developed, nor could he identify what bothered him about snakes, except perhaps something about their movement. Mr. D decided to move back to the city and had just put his house up for sale when he presented for treatment.

Mr. D had a specific phobia of snakes and reported no other significant problems with anxiety. Before he began behavioral treatment, a full assessment of his fear was conducted. A hierarchy of feared situations was generated ranging from moderately anxiety provoking tasks (e.g., looking at a photograph of a snake) to extremely difficult tasks (e.g., touching a snake). In addition, a behavioral approach was conducted during which it was discovered that Mr. D could stand no closer than 10 feet from a live snake in an aquarium. In addition, during the behavioral approach test he became aware that his main anxious thought was that the snake would touch him and perhaps bite him. His fear tended to increase when the snake looked in his direction or moved in the aquarium.

Mr. D was treated during two sessions of therapist-assisted exposure, each lasting 120 minutes. During the sessions, he practiced the various tasks on his hierarchy and continued to do so even when his fear was overwhelming. Each step was first demonstrated by the therapist. By the end of two sessions, Mr. D was able to look at, touch, and hold a snake with minimal anxiety. At 1-month follow-up, he reported that he no longer avoided situations in which he might see snakes and had decided to continue living in his house.

**Comparison of DSM-IV/ICD-10 Diagnostic Criteria**

The ICD-10 Diagnostic Criteria for Research for Social Phobia specify that at least two symptoms of anxiety (i.e., from the list of 14 panic symptoms) be present together on at least one occasion along with at least one of the following anxiety symptoms: blushing or shaking, fear of vomiting, and urgency or fear of micturition or defecation. Furthermore, these anxiety symptoms must be “restricted to, or predominated in, the feared situations or contemplation of the feared situations.” In contrast, the DSM-IV-TR criteria do not specify any particular types of anxiety symptoms nor is any restriction placed on whether anxiety can occur in situations other than social situations.

For specific phobia, the ICD-10 Diagnostic Criteria for Research also specify that the anxiety symptoms be “restricted to, or predominated in, the feared situations or contemplation of the feared situation.” DSM-IV-TR again does not impose any such restriction.

Definition and Diagnostic Features

Obsessive–compulsive disorder (OCD) is an intriguing and often debilitating syndrome characterized by the presence of two distinct phenomena: obsessions and compulsions. Obsessions are intrusive, recurrent, unwanted ideas, thoughts, or impulses that are difficult to dismiss despite their disturbing nature. Compulsions are repetitive behaviors, either observable or mental, that are intended to reduce the anxiety engendered by obsessions. Obsessions or compulsions that clearly interfere with functioning and/or cause significant distress are the hallmark of OCD.

Although OCD was originally considered rare, findings from the Epidemiologic Catchment Area (ECA) survey in 1984 demonstrated that OCD was 50–100 times more common than had been previously believed (Myers et al. 1984). With increasing recognition of OCD, both in the mental health field and in the media, many individuals with OCD have pursued treatment for this disorder. This has led to systematic investigation of clinical features such as symptom subtype, course, comorbidity, and the role of insight both descriptively and as moderators of treatment response.

These studies, conducted over the two decades, have greatly furthered our understanding of the clinical characteristics of this disorder. OCD is now considered a relatively common disorder that usually has its onset during puberty, although it may begin as early as age 2 years and infrequently begins after age 35 years. Women develop OCD slightly more often than men. Earlier studies found that the course of OCD is usually chronic, with symptom severity waxing and waning over time. However, those studies, which had a number of methodological limitations, were conducted prior to the availability of effective treatments for this disorder.

More recent evidence suggests that some individuals have a more episodic and favorable course.

Several large studies have found that the most common obsession is contamination, and the most common compulsion is checking. However, most individuals with this disorder have multiple obsessions and compulsions over time. A number of psychiatric disorders co-occur with OCD, major depressive disorder being most frequent. Comorbidity with tic disorders is well established. That association plus a familial relationship between OCD and tic disorders has led to suggestions that OCD has a specific-tic–related phenotype. There has been considerable interest in the role of insight, or awareness, in OCD. An ability to recognize the senselessness of the obsessions and the ability to resist obsessional ideas have been considered fundamental components of OCD. However, research findings from the past two decades have demonstrated a continuum of insight in this disorder, which ranges from excellent (i.e., complete awareness of the senselessness of the content of the obsessions), through poor insight, to delusional thinking (i.e., the obsessions are held with delusional conviction) (Eisen and Rasmussen 1993, Leliot et al. 1988, Foa and Kozak 1995). To reflect these findings, the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) established a specifier—with poor insight—and also noted that, in cases of delusional OCD, an additional diagnosis of delusional disorder or psychotic disorder not otherwise specified may be appropriate (American Psychiatric Association 1994).

OCD’s clinical presentation is characterized by phenomenological subtypes based on the content of the obsessions and corresponding compulsions. The list of subtypes in the Yale–Brown Obsessive–Compulsive Scale (Y-BOCS)

(Table 71–1) was generated on the basis of clinical interviews with OCD patients in the 1980s (Goodman et al. 1989a). These subtypes are remarkably consistent with phenomenological descriptions in the psychiatric literature beginning with scrupulosity in the 15th century:

William of Oseney…read two or three books of Religion and devotion very often…(he) had read over those books 3 hours every day. In a short time he had read over those books three times more help; (He) began to think…that now he was to spend 6 hours every day in reading those books, because he had now read them over six times. He presently considered that…he must be tied to 12 hours every day (Hunter and Macalpine 1982).

The basic types of obsessions and compulsions seem to be consistent across cultures (Rasmussen and Eisen 1992). The most common obsession is fear of contamination, followed by pathological doubt, a need for symmetry, and aggressive obsessions (Figure 71–1). The most common compulsion is checking, which is followed by washing, the need to maintain symmetry, the need to ask or confess, and counting (Figure 71–2). Children with OCD present most commonly with washing compulsions, which are followed by repeating rituals (Swedo et al. 1989).

Most patients have multiple obsessions and compulsions over time, with a particular fear or concern dominating the clinical picture at any one time. The presence of obsessions without compulsions, or compulsions without obsessions, is unusual. In the DSM-IV OCD field trial of 431 patients, only 2% had only obsessions and 2% had only compulsions; the remaining 96% endorsed both obsessions and compulsions (Foa and Kozak 1995). Patients who appear to have obsessions without compulsions frequently have unrecognized reassurance rituals or mental compulsions, such as repetitive, ritualized praying, in addition to their obsessions. Pure compulsions are also unusual in adults, although they do occur in children, especially in the young (e.g., 6–8 years of age; Swedo et al. 1989). Most people have both mental and behavioral compulsions; in the DSM-IV field trial 79.5% reported having both mental and behavioral compulsions, 20.3% had behavioral compulsions only, and 0.2% had only mental compulsions.

The search for whether specific obsessions and compulsions have predictive value in terms of treatment response, biologic markers, or genetic transmission has not been particularly fruitful. There has been considerable interest in...

Figure 71–2 Compulsive symptoms at the time of initial evaluation in 550 patients.
exploring whether certain clusters of obsessions and compulsions represent specific OCD phenotypes. A number of studies have addressed this question systematically using the Y-BOCS Symptom Checklist to identify groups of obsessions and compulsions that cluster together on factor analysis. Several studies have found between 3 and 5 such symptom dimensions: symmetry/ordering, hoarding, contamination/cleaning, aggressive obsessions/checking, and sexual/religious obsessions (reviewed by Mataix-Cols et al. 2005). The symmetry dimension has been associated with comorbid tic disorder; in one study, patients who scored high on this dimension had a relative risk for chronic tic disorder that was 8.5 times higher than those scoring low on this factor (Leckman et al., reviewed in Mataix-Cols et al. 2005). It appears that these symptom dimensions are stable over time; that is, although a patient’s specific obsessions and compulsions may change over time, new obsessions and compulsions that develop are often within the same symptom dimension as the previous symptoms (Mataix-Cols et al. 2005). A study using positron emission tomography (PET scans) to evaluate neural correlates to specific areas of the brain for various symptom dimensions suggests that dysfunction in separate regions of the brain, such as the striatum and prefrontal cortex, may mediate different symptom dimensions. (Rauch et al., reviewed in Mataix-Cols et al. 2005).

Data were analyzed from a number of placebo-controlled serotonin reuptake inhibitor (SRI) treatment studies to assess whether symptom factors or dimensions were associated with treatment response (Mataix-Cols et al. 2005). No clear pattern emerged except that patients with hoarding obsession had a significantly poorer response to SRIs. Whether these identified dimensions are associated with response to behavioral treatment, biological markers, or genetic transmission has only begun to be investigated.

The following descriptions of some common obsessions and compulsions illustrate the clinical presentation of these symptoms. In some cases, a particular symptom may belong to more than one “type” of obsessive or compulsive grouping. For instance, a patient who has concerns about cancer may have hand washing as a compulsion related to her somatic obsession. However, if the patient also washes repeatedly to avoid contamination in general, not just for cancer, she would have both contamination and somatic obsessions and compulsions.

**Contamination**

Contamination obsessions are the most frequently encountered obsessions in OCD. Such obsessions are usually characterized by a fear of dirt or germs. For example, a 38-year-old computer programmer was excessively preoccupied with the thought that her apartment would become dirty. She had never allowed a visitor into her apartment or worn a coat during the winter, because she feared that she would be unable to protect her apartment from dirt brought inside by either a visitor or a coat. To avoid contamination, she washed her clothes and showered immediately on entering her home.

Contamination fears may also involve toxins or environmental hazards (e.g., asbestos or lead) or bodily waste or secretions. Patients usually describe a feared consequence of contacting a contaminated object, such as spreading a disease or contracting an illness themselves. Occasionally, however, the fear is based not on a fear of disease but on a fear of the sensory experience of not being clean. The content of the contamination obsession and the feared consequence commonly changes over time; for example, a fear of cancer may be replaced by a fear of a sexually transmitted disease.

Many patients with contamination fears use avoidance to prevent contact with contaminants, as is illustrated by a 58-year-old housewife who spent the entire day sitting in a chair to avoid touching anything in the house that might be dirty. In some cases, a specific feared object and associated avoidance become more generalized. For example, a woman with a fear of acquired immunodeficiency syndrome (AIDS) initially avoided anything that looked like dried blood but eventually avoided anything red.

Excessive washing is the compulsion most commonly associated with contamination obsessions. This behavior usually occurs after contact with the feared object; however, proximity to the feared stimulus is often sufficient to engender severe anxiety and washing compulsions, even though the contaminated object has not been touched. Most patients with washing compulsions perform these rituals in response to a fear of contamination, but these behaviors occasionally occur in response to a drive for perfection or a need for symmetry. Some patients, for example, repeatedly wash themselves in the shower until they feel “right” or must wash their right arm and then their left arm the same number of times.

**Need for Symmetry**

Need for symmetry is a term that describes a drive to order or arrange things perfectly or to perform certain behaviors symmetrically or in a balanced way. Patients describe an urge to repeat motor acts until they achieve a “just right” feeling that the act has been completed perfectly. Patients with a prominent need for symmetry may have little anxiety but rather describe feeling unsettled or uneasy if they cannot repeat actions or order things to their satisfaction. In addition to a need for perfection, the drive to achieve balance or symmetry may be connected with magical thinking. For example, a 22-year-old college student felt compelled to walk across doorway thresholds exactly in the center to prevent something terrible from happening to his parents. The desire to “even up” or balance movements may be present in patients with tapping or touching rituals. Such a patient may, for example, feel that the right side of the chair must be tapped after the left side has been tapped. Such urges and behaviors are frequently seen in patients with comorbid tic disorders (Leckman et al. 1994, reviewed in Mataix-Cols et al. 2005), who may, for example, describe an urge to tic on the right side of their body after experiencing a tic on the left side.

Patients with a need for symmetry frequently present with obsessional slowness, taking hours to perform acts such as grooming or brushing their teeth. A 23-year-old cook spent 2 hours a day brushing his teeth in a symmetrical fashion and as a result developed gingival erosion. He reported being exquisitely aware of exactly how the toothbrush touched each surface of each tooth and of how he placed the toothbrush and cup down after finishing. He was unable to describe any obsession or fear about not performing this task adequately but rather felt unable to stop until he had brushed completely, despite warnings from his dentist about the harm he was causing.
Somatic Obsessions
Patients with somatic obsessions are worried about the possibility that they have or will contract an illness or disease. In the past, the most common somatic obsessions consisted of fears of cancer or venereal diseases. However, a fear of developing AIDS has become increasingly common. Checking compulsions consisting of checking and rechecking the body part of concern, as well as reassurance seeking, are commonly associated with this fear. For example, a 29-year-old firefighter spent 3 hours a day examining his throat in the mirror and palpating his lymph nodes to determine whether he had throat cancer. He also repeatedly asked his wife whether she thought his throat looked normal. While it may be difficult to distinguish the somatic obsessions of OCD from those of hypochondriasis, somatic obsessions in OCD usually involve compulsive behaviors of some sort done by the patient, not necessarily seeking medical opinions about the feared illness (see below for more elaboration).

Sexual and Aggressive Obsessions
People with sexual or aggressive obsessions are plagued by fears that they might harm others or commit a sexually unacceptable act such as molestation. Often, they are fearful not only that they will commit a dreadful act in the future but also that they have already committed the act. Patients are usually horrified by the content of their obsessions and are reluctant to divulge them. It is striking that the content of these obsessions tends to consist of ideas that patients find particularly abhorrent. A 32-year-old librarian who wanted to be a good mother had intrusive thoughts of stabbing her daughter. The horror and revulsion that she experienced in response to this image is typical of patients’ reactions to their aggressive and sexual thoughts.

Patients with these highly distressing obsessions frequently have checking and confession or reassurance rituals. They may report themselves to the police or repeatedly seek out priests to confess their imagined crimes. For example, a 63-year-old mother of five children and seven grandchildren felt compelled to confess to her priest that she might have had a sexual thought or feeling while drying herself after showering. A 29-year-old secretary constantly checked the local news to be certain that she had not murdered someone. An unsolved murder case caused her tremendous anxiety and led to extensive reassurance rituals.

Pathological Doubt
Pathological doubt is a common feature of patients with OCD who have a variety of different obsessions and compulsions. Individuals with pathological doubt are plagued by the concern that, as a result of their carelessness, they will be responsible for a dire event. They may worry, for example, that they will start a fire because they neglected to turn off the stove before leaving the house. Although many patients report being fairly certain that they performed the act in question (e.g., locking the door, unplugging the hairdryer, paying the correct amount on a bill), they cannot dismiss the nagging doubt “What if?”

Such patients often describe doubting their own perceptions. A 42-year-old man felt incapable of throwing grocery bags away because he feared he might not have completely emptied them. Immediately after staring into an empty bag, he inevitably thought, “What if I missed something important in there?” A 33-year-old lawyer was unable to mail anything because she feared she had inadvertently placed written misinformation inside the envelope.

Excessive doubt and associated feelings of excessive responsibility frequently lead to checking rituals. For example, individuals may spend several hours checking their home before they leave. As with contamination obsessions, pathological doubt can lead to marked avoidance behavior. Some patients become housebound to avoid the responsibility of potentially leaving the house unlocked.

Pathological doubt is also embedded in the cognitive framework of a number of other obsessions. Patients with aggressive obsessions may be plagued by the doubt that they inadvertently harmed someone without knowing that they did so. For example, a young mother did not allow her children to have friends sleep at her house because she feared she might harm them during the night. Although she agreed that it was preposterous to think that she might commit a violent act without being aware of it, she nonetheless stated that she “did not want to take a chance,” and she was unable to dismiss her nagging worry and doubt.

Insight
An awareness of the senselessness or unreasonableness of obsessions (often referred to as insight) and the accompanying struggle against the obsessions (referred to as resistance) have generally been considered fundamental components of OCD. However, during the past century there have been numerous descriptions of patients with OCD who are completely convinced of the reasonableness of their obsessions and need to perform compulsions. Patients with OCD may have varying degrees of insight and resistance, with obsessive–compulsive psychosis at one extreme of a hypothesized continuum.

One study that investigated the range of insight in OCD used an interview that evaluated several insight-related parameters, including the fixity of beliefs underlying the obsession, bizarreess, resistance, and degree of control (Lelliot et al. 1988). The fixity dimension included several constructs: strength of the belief in the feared situation, how the patient thought others viewed the belief, and the patient’s response to evidence that contradicted the belief. A full range of responses was found in the 43 patients assessed, which led the authors to conclude that good insight is not necessarily present and that insight spans a spectrum from good to absent (i.e., delusional thinking).

More recently, degree of insight in OCD was addressed during the DSM-IV field trial in which patients were asked if they feared consequences other than anxiety if they did not perform their compulsions (Foaa and Kozak 1995). Fifty-eight percent believed that harmful consequences would occur. The degree of certainty that their obsessions were reasonable ranged across the entire spectrum of insight: 30% were uncertain whether they actually needed to perform their compulsions to avoid harm; however, 4% were certain, and 26% were mostly certain. Again, this finding supports the notion that patients with OCD do not always maintain good insight but rather have varying degrees of insight.

Although patients may be aware that their obsessions are excessive—that is, recognizing that they spend too much time thinking about them—they may have little insight into the fact that the belief underlying their obsession (e.g., that
they will get cancer from stepping on a chemically treated lawn) is senseless, unreasonable, or unrealistic. To reflect these findings, DSM-IV-TR established a new OCD specifier, with poor insight. This specifier applies to “an individual who, for most of the time in the current episode, does not recognize that the obsessions or compulsions are excessive or unreasonable.” DSM-IV-TR also acknowledges that the beliefs that underlie OCD obsessions can be delusional and notes that in such cases an additional diagnosis of delusional disorder or psychotic disorder not otherwise specified may be appropriate.

Despite these changes, there was no generally accepted, reliable, and valid method to assess degree of insight. To address the need for a scale that measures insight in OCD and other psychiatric disorders, Eisen and Phillips developed the Brown Assessment of Beliefs Scale, a semistructured clinician-administered interview with specific probes and anchors that measure various dimensions of delusional-ality (Eisen et al. 1998). Items assess dimensions such as conviction, perception of others’ views of the belief, fixity, and insight (awareness that obsessions and compulsions are caused by a psychiatric illness). Combining data from a number of studies, 20–25% of individuals with OCD at some point during their illness are fairly convinced that their obsessions are realistic and that consequences other than anxiety would occur if they did not perform their compulsions. Nonetheless, most people with OCD are aware that other people think their symptoms are unrealistic and that the obsessions are caused by a psychiatric illness.

Whether insight is an important predictor of prognosis and treatment response is an intriguing issue that has received little investigation. However, it appears that patients with poor insight or overvalued ideas may not respond as well to behavioral therapy as patients with good insight. In the only study that has, to our knowledge, assessed whether insight predicts medication response, patients with poor insight at study baseline were just as likely to have a response of OCD symptoms to open-label sertraline as those with good to excellent insight. In addition, insight improved with sertraline treatment during this 16-week study (Eisen et al. 2001).

More studies are needed to determine the effect of insight on treatment response. For example, to our knowledge no studies have assessed whether adding an antipsychotic to an SRI is more effective in patients with poor insight than in those with good insight. Studies that assess the impact of insight on compliance, refusal of, and response to behavioral therapy are also needed.

Demographics—Marital Status
In a study of 250 subjects with OCD 52% were married, 43% were never married, and 5% were divorced (Rasmussen and Eisen 1992). The percentage of patients who had never married was significantly higher than that of age-matched controls. In the BNPMS, 36% of subjects with OCD lived alone, which was more than twice the rate of nonneurotic controls (Torres et al. 2006a). However, a study comparing marital status in probands with OCD and an age-matched group of patients with major depressive disorder found no significant differences between the two groups (Coryell 1981). Although marital status was not found to be a predictor of course in a number of follow-up studies, a prospective study of 107 subjects with OCD found that being married significantly increased the probability of partial remission, with married patients more than twice as likely to remit as unmarried ones (Steketee et al. 1999). Furthermore, rehospitalization after 6–8 years of follow-up after cognitive–behavioral therapy (CBT) combined with either fluvoxamine or placebo was associated with living without a partner (Ruder et al. 2005).

**Epidemiology**
Since the 15th century, the psychiatric literature has contained striking descriptions of patients with debilitating obsessions and compulsions. Until the mid-1980s, however, OCD was considered extremely rare. This perception was based on studies from the 1950s and 1960s that examined the frequency of psychiatric diagnoses in inpatient and outpatient settings. The results of a large psychiatric epidemiological study, the national ECA survey, conducted in the US in 1984, painted a different picture of OCD’s prevalence. This study found that OCD was the fourth most common psychiatric disorder (after the phobias, substance use disorders, and major depressive disorder), with a prevalence of 1.6% over 6 months and a lifetime prevalence of 2.5% (Myers et al. 1984). Although the ECA survey has been criticized as overestimating OCD’s prevalence, a subsequent study in the US and several epidemiological studies in other countries have supported its findings. Using the same instrument as the ECA, studies have been done in diverse cultures, including Puerto Rico, Canada, Germany, Taiwan, New Zealand, and Korea, as part of the Cross National Collaborative Group (Weissman et al. 1994). The lifetime (range 1.9–2.5%) and annual (range 1.1–1.8%) prevalence rates of OCD were remarkably consistent across countries with the exception of Taiwan. The rates in Taiwan were substantially lower than in all the other sites, paralleling Taiwan’s low rates of other psychiatric disorders. A recent epidemiological study in the UK, the British National Psychiatric Morbidity Survey of 2000 (BNPMS), used the Clinical Interview Schedule—Revised and ICD-10 criteria.

**ICD-10 Criteria for Obsessive-Compulsive Disorder**

**F42 Obsessive-compulsive disorder**
The essential feature is recurrent obsessional thoughts or compulsive acts. Obsessional thoughts are ideas, images, or impulses that enter the patient’s mind again and again in a stereotyped form. They are almost invariably distressing and the patient often tries, unsuccessfully, to resist them. They are, however, recognized as his or her own thoughts, even though they are involuntary and often repugnant. Compulsive acts or rituals are stereotyped behaviours that are repeated again and again. They are not inherently enjoyable, nor do they result in the completion of inherently useful tasks. Their function is to prevent some objectively unlikely event, often involving harm to or caused by the patient, which he or she fears might otherwise occur. Usually, this behaviour is recognized by the patient as pointless or ineffectual and repeated attempts are made to resist.
Anxiety is almost invariably present. If compulsive acts are resisted the anxiety gets worse.

**Includes:** anankastic neurosis, obsessive-compulsive neurosis

**Excludes:** obsessive-compulsive personality (disorder)

**F42.0** Predominantly obsessional thoughts or ruminations

These may take the form of ideas, mental images, or impulses to act, which are nearly always distressing to the subject. Sometimes the ideas are an indecisive, endless consideration of alternatives, associated with an inability to make trivial but necessary decisions in day-to-day living. The relationship between obsessional ruminations and depression is particularly close and a diagnosis of obsessive-compulsive disorder should be preferred only if ruminations arise or persist in the absence of a depressive episode.

**F42.1** Predominantly compulsive acts [obsessional rituals]

The majority of compulsive acts are concerned with cleaning (particularly handwashing), repeated checking to ensure that a potentially dangerous situation has not been allowed to develop, or orderliness and tidiness. Underlying the overt behaviour is a fear, usually of danger either to or caused by the patient, and the ritual is an ineffectual or symbolic attempt to avert that danger.

**F42.2** Mixed obsessional thoughts and acts

**F42.8** Other obsessive-compulsive disorders

**F42.9** Obsessive-compulsive disorder, unspecified

In this sample, the weighted prevalence of OCD was 1.1% (Torres et al. 2006a).

**Comorbidity**

**Major Depression**

OCD frequently occurs in association with other Axis I disorders. In a study of 100 patients with primary OCD, 67 had a lifetime history of major depressive disorder, and 31 had symptoms that met criteria for current major depressive disorder (Rasmussen and Eisen 1991). In the BNPMS, 36% of subjects with OCD met criteria for depressive episode (Torres et al. 2006a). Although it may be difficult to distinguish a primary from a secondary diagnosis, some individuals with OCD view their depressive symptoms as occurring secondary to the demoralization and hopelessness accompanying their OCD and report that they would not be depressed if they did not have OCD. However, others view their major depressive symptoms as occurring independently of their OCD symptoms, which may be less severe when they cycle into an episode of major depression, because they feel too apathetic to be as concerned with their obsessions and too fatigued to perform compulsions. Conversely, OCD symptoms may intensify during depressive episodes.

**Tic Disorders**

Although findings have varied, the generally accepted frequency of tic disorders in patients with OCD is far higher than in the general population, with a rate of approximately 5–10% for Tourette’s Disorder and 20% for any tic disorder (Leonard et al. 1992). Conversely, patients with Tourette’s disorder have a high rate of comorbid OCD, with 30–40% reporting obsessive–compulsive symptoms (Lees et al. 1984, Robertson et al. 1988). The likelihood of childhood onset of OCD is greater in this group, and the presence of tics is associated with more severe OCD symptoms in children (Leonard et al. 1992). There is an increased rate of both OCD and tic disorders in the first-degree relatives of OCD probands with a family lifetime history of tics (Nestadt et al. 2000b), and an increased frequency of tic disorders in the first-degree relatives of OCD probands compared to controls (Grados et al. 2001). There are also phenomenologic observations that link OCD and tic disorders. Individuals with both OCD and tics have several features that distinguish them from individuals with OCD alone. They more frequently have symmetry, ordering and arranging, and hoarding compulsions, and they more frequently try to attain a “just right” feeling. These data strengthen the notion that tic disorders and OCD are highly related. In fact, it has been suggested that tic disorders are an alternative expression or phenotype of the familial OCD subtype (Grados et al. 2001).

**Anxiety Disorders**

Anxiety disorders frequently coexist with OCD, with relatively high lifetime rates of specific phobia (22%), social phobia (18%), and panic disorder (12%) in patients with OCD (Rasmussen and Eisen 1991). In one study, 17 of 100 subjects with OCD had a lifetime history of an eating disorder (Rasmussen and Eisen 1991). Conversely, in 93 subjects with an eating disorder, 37 had symptoms that met criteria for comorbid OCD (Rubenstein et al. 1992). In 114 epidemiologically ascertained subjects from the UK BNPMS study, subjects with OCD had significantly more comorbid conditions than subjects with other neuroses. These included generalized anxiety disorder (31.4%), agoraphobia or panic disorder (22.1%), social phobia (17.3%), and specific phobia (15.1%). There were no significant gender differences in either overall comorbidity or the comorbidity prevalence of individual neurotic disorders (Torres et al. 2006a).

**Psychotic Disorders**

It has long been noted that the co-occurrence of OCD symptoms in patients with psychotic disorders is more than would be expected by chance. Furthermore, it has more recently been suggested that the admixture of psychotic and OCD symptoms may represent a “schizo-obsessive” subtype. One of the complications in studying this issue is that it is often difficult to differentiate delusions from obsessions with poor insight (reviewed by Bottas et al. 2005). In the BNPMS, 15 of 114 OCD subjects screened positive for possible psychosis (12.7%). Of these, 3 (15.8%) or 2.6% of all OCD subjects met ICD-10 criteria for schizophrenia in the past year (Torres et al. 2006a). This is consistent with a previous study, in which 14% (N = 67) of 475 OCD subjects had psychotic or psychotic-like symptoms (Eisen and Rasmussen 1993). These 67 subjects were quite heterogeneous: 18 (4% of the larger cohort) had comorbid schizophrenia, 8 (2%...
had comorbid delusional disorder unrelated to OCD, and 14 (3%) had comorbid schizotypal personality disorder. In the remaining 27 patients (6% of the larger cohort), the only psychotic symptom was a delusional conviction about the reasonableness of the obsessions (i.e., delusional OCD or OCD without insight). Of interest, the 27 subjects without insight regarding their OCD symptoms were similar to the subjects without any psychotic symptoms (i.e., OCD with insight) in terms of epidemiological and clinical features, such as course of illness. More recently, a longitudinal study of 293 adults with primary OCD reported a lower frequency of comorbid psychotic symptoms at intake with a lifetime frequency of 2.7% (n = 8) and a current frequency of 2% (n = 6) (Pinto et al. 2006).

In contrast, several studies of OCD and comorbid schizophrenia found that compared to subjects with OCD alone, those with comorbid schizophrenia have a worse prognosis in terms of long-term outcome (social relations, employment, psychopathology, and global functioning; Fenton and McGlashan 1986). Similarly, treatment studies of patients with OCD and comorbid schizotypal personality disorder have shown a poorer prognosis and poorer response to psychotropic medications for the comorbid group (Jenike et al. 1986). Thus, it appears important to differentiate OCD plus a comorbid psychotic disorder, which may have a relatively poor outcome, from delusional OCD, which may be more similar to OCD with insight and without comorbid psychosis.

Retrospective follow-up studies that have examined the subsequent development of schizophrenia in patients with OCD have had varying results, with rates ranging from 0.7% to as high as 12.3% (reviewed by Goodwin et al. 1969). These studies were, however, methodologically limited in that none were prospective, diagnoses were made by chart review, and standardized diagnostic criteria were not used, which probably resulted in the inclusion of affective psychoses. In reviewing this literature, Goodwin et al. (1969) concluded that people with OCD were at no greater risk for developing schizophrenia than the general population. Conversely, studies of patients with schizophrenia or schizoaffective disorder have found rates of OCD ranging from 8 to 46%. This strikingly large range is most likely due to the OCD criteria used (i.e., subclinical OCD symptoms vs. OCD symptoms severe enough to cause significant impairment or distress) (Eisen et al. 1997, Porto et al. 1997, Berman et al. 1995). Regardless, it is clear that a significant number of people with schizophrenia have OCD symptoms that require assessment and may benefit from treatment.

Personality Disorders

The relationship between OCD and personality disorders, particularly obsessive–compulsive personality disorder (OCPD), has received considerable attention. Early observations noted the presence of OCPD traits in patients with OCD. Systematic studies have yielded inconsistent findings. In the British BNPMS, 76% of all OCD subjects screened positive for any personality disorder (Torres et al. 2006b). In a study of 96 subjects with OCD that used the Structured Clinical Interview for DSM-III personality disorders (SCID-II), 36 had a personality disturbance that met criteria for one or more personality disorders (Baer et al. 1990a). Dependent (N = 12), histrionic (N = 9), and obsessive–compulsive (N = 6) personality disorders were most frequent. However, a study that used the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) criteria found that OCPD was present in 25 of 59 subjects with OCD; the higher rate of OCPD found with the DSM-III-R criteria may reflect changes in the criteria set between DSM-III and DSM-III-R. Another study of the rate of OCPD in first-degree relatives of OCD probands found a similar frequency of OCPD in people with OCD. OCPD occurred in 32% of the probands and was twice as frequent in the relatives of OCD probands as in relatives of control probands (Samuels et al. 2000), suggesting that OCPD may share a common familial etiology with OCD. Regarding the converse, in a recent study of 629 subjects with personality disorders, 20% of patients with OCPD met DSM-IV-TR criteria for OCD, which was more frequent than any other personality disorder (Eisen et al. 2006).

Although personality disorders are considered to be stable over time, one study found that of 17 OCD patients with a personality disorder, 9 of the 10 treatment responders no longer met criteria for either avoidant or dependent personality disorder after successful pharmacotherapy, raising the question of whether these personality disorders actually represented a coping style in response to OCD (Ricciardi et al. 1992). And an alternative explanation is that pharmacotherapy may have the potential of ameliorating certain aspects of the personality disorder.

Course

Age at onset usually refers to the age when OCD symptoms (obsessions and compulsions) reach a severity level wherein they lead to impaired functioning or significant distress or are time-consuming (i.e., meet DSM-IV-TR criteria for the disorder). Reported age at onset is usually during late adolescence. In one study drawn from an OCD clinic sample (N = 560), the onset for males occurred significantly earlier than for females (19.5 ± 9.2 years vs. 22.0 ± 9.8 years). In this study, 83% of patients experienced the onset of significant symptoms between ages 10 and 24 years, whereas less than 15% experienced onset after age 35 years (Rasmussen and Eisen 1998). People with OCD, however, usually describe the onset of minor symptoms in childhood, well before the onset of symptoms meeting full criteria for the disorder.

Earlier age at onset has been associated with an increased rate of OCD in first-degree relatives (Nestadt et al. 2000a). These data suggest that there is a familial type of OCD characterized by early onset. Age at onset of OCD may also be a predictor of course. The vast majority of patients report a gradual worsening of obsessions and compulsions prior to the onset of full-criteria OCD, which is followed by a chronic course (see later). However, Swedo and colleagues have described a subtype of OCD that begins before puberty and is characterized by an episodic course with intense exacerbations. Exacerbations of OCD symptoms in this subtype have been linked with group A beta-hemolytic streptococcal infections, which has led to the subtype designation of pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS). In their study of 50 children with PANDAS, the average age of onset was 7.4 years. Whether the course of illness in patients with PANDAS continues to be episodic into adulthood, or, as is the case with postpubertal onset,
Differential Diagnosis

OCD is sometimes difficult to distinguish from certain other disorders. Obsessions and compulsions may appear in the context of other syndromes, which can raise the question whether the obsessions and compulsions are a symptom of another disorder or whether both OCD and another disorder are present (see section on comorbidity). A general guideline is that if the content of the obsessions is not limited to the focus of concern of another disorder (e.g., an appearance concern, as in body dysmorphic disorder, or food concerns, as in an eating disorder) and if the obsessions or compulsions are preoccupying as well as distressing or impairing, OCD should generally be diagnosed.

Diagnostic dilemmas may also arise when it is unclear whether certain thoughts are obsessions or whether, instead, they are ordinary worries, ruminations, overvalued ideas, or delusions. In a similar vein, questions may develop about whether certain behaviors constitute true compulsions or whether they should instead be conceptualized as impulses, tics, or addictive behaviors.

Obsessive–Compulsive Disorder Versus Other Anxiety Disorders

Both OCD and the other anxiety disorders are characterized by the use of avoidance to manage anxiety. However, OCD is distinguished from these disorders by the presence of compulsions. For OCD patients with preoccupying fears or worries but no rituals, several other features may be useful in establishing the diagnosis of OCD. In social phobia and specific phobia, fears are circumscribed and related to specific triggers (in specific phobia) or social situations (in social phobia). Although circumscribed situations may initially trigger obsessions and compulsions in OCD, triggers in OCD become more generalized over time, unlike the triggers in social and specific phobias, in which the evoking situations remain circumscribed.

As many as 60% of people with OCD experience full-blown panic symptoms. However, unlike panic disorder, in which panic attacks occur spontaneously, panic symptoms occur in OCD only during exposure to specific feared triggers such as contaminated objects. The worries that are present in generalized anxiety disorder (GAD) are more ego syntonic and involve an exaggeration of ordinary concerns, whereas the obsessional thinking of OCD is more intrusive and is limited to a specific obsession (e.g., contamination, blasphemy), and usually has an irrational, senseless, or unreasonable quality. Also, whereas the worry of GAD is considered primarily “thought-like” in nature, obsessional symptoms may consist of thoughts, impulses, or images.

Obsessive–Compulsive Disorder Versus Psychotic Disorders

One question is how to differentiate OCD from psychotic disorders such as schizophrenia and delusional disorder. Another question is how to distinguish OCD with insight from OCD without insight (delusional OCD). One distinguishing feature between OCD and the psychotic disorders is that the latter are not characterized by prominent ritualistic behaviors. If compulsions are present in a patient with prominent psychotic symptoms, the possibility of a comorbid OCD diagnosis should be considered. Furthermore, although schizophrenia may be characterized by obsessional thinking, other characteristic features of the disorder, such as prominent hallucinations or thought disorder, are also present. With regard to delusional disorder, paranoid and grandiose concerns are generally not considered to fall under the OCD rubric. However, some other types of delusional disorders, such as the somatic and jealous types, seem to bear a close resemblance to OCD and are not always easily distinguished from it. It will be interesting to see whether future research indicates that certain types of somatic delusional disorders (e.g., the delusional variant of hypochondriasis) and the jealous type of delusional
disorder (also referred to as pathological jealousy) are actually variants of OCD.

The second issue noted above—how to distinguish OCD with insight from OCD without insight—is complex. As previously discussed, insight in OCD is increasingly being recognized as spanning a spectrum from good to poor to absent. Both clinical observations and research findings indicate that some individuals hold their obsessional concerns with delusional intensity and believe that their concerns are reasonable. In DSM-IV-TR, delusional OCD may be double coded as both OCD and delusional disorder or as both OCD and psychotic disorder not otherwise specified; in other words, patients with delusional OCD would receive both diagnoses. This double coding reflects the fact that it is unclear whether OCD with insight and OCD without insight constitute the same or different disorders. Further research using validated scales to assess insight in OCD is needed to shed light on this question.

**Obsessive–Compulsive Disorder Versus Impulse Control Disorders**

Differential diagnosis questions have been raised with regard to kleptomania, trichotillomania, pathological gambling, and other disorders involving impulsive behaviors. Several features have been said to distinguish these disorders from OCD. For example, OCD compulsions generally have no gratifying element, although they do diminish anxiety. In contrast, behaviors of the impulse control disorders are usually gratifying, pleasurable, and rewarding. In addition, the affective state that drives the behaviors associated with these disorders may differ. In OCD, fear is frequently the underlying drive that leads to compulsions, which, in turn, decrease anxiety. In the impulse control disorders, patients frequently describe heightened tension, but not fear, preceding an impulsive behavior. However, OCD and the impulse control disorders have some features in common. Research is ongoing to explore the relationship between OCD and the impulse control disorders by examining similarities and differences in treatment response, biological markers, familial transmission, and other external validators (Dell’Osso et al. 2006).

**Obsessive–Compulsive Disorder Versus Tourette’s Disorder**

Complex motor tics of Tourette’s disorder may be difficult to distinguish from OCD compulsions. Both tics and compulsions are preceded by an intrusive urge and are followed by feelings of relief. However, OCD compulsions are usually preceded by both anxiety and obsessional concerns, whereas, in Tourette’s disorder, the urge to perform a tic is not preceded by an obsessional fear. This distinction breaks down to some extent when considering the “just right” perceptions of some patients with OCD. The “just right” perception refers to the need to perform a certain motor action, such as touching, tapping, checking, ordering, arranging, or counting, until it feels right. Determining when an action has been performed enough or perfectly may depend on tactile, visual, or auditory perceptions. In a study of patients with Tourette’s disorder and OCD symptoms, most patients could distinguish between the mental urge to do something repeatedly until it felt right and a physical urge to perform a motor tic. However, it is sometimes difficult for psychiatrists to distinguish between complex tics and compulsions, especially when a patient has both disorders (Miguel et al. 1995).

**Obsessive–Compulsive Disorder Versus Hypochondriasis**

Fears of illness that occur in OCD, referred to as somatic obsessions, may be difficult to distinguish from hypochondriasis. Usually, however, patients with somatic obsessions have other current or past classic OCD obsessions unrelated to illness concerns. Patients with OCD also often engage in classic OCD rituals, such as checking or reassurance seeking, in an attempt to diminish their illness concerns. Unlike patients with OCD, patients with hypochondriasis experience somatic and visceral sensations. Although insight and resistance have been used to distinguish OCD from hypochondriasis, with the concern in hypochondriasis being said to be ego syntonic (realistic and justified) and that of OCD to be ego dystonic (unacceptable and undesirable thoughts, actions, or both), studies have demonstrated a range of insight in OCD. Attempting to differentiate these disorders by degree of insight or ego syntonicity may, therefore, be of limited usefulness.

**Obsessive–Compulsive Disorder Versus Body Dysmorphic Disorder**

Body dysmorphic Disorder (BDD), a preoccupation with an imagined or slight defect in appearance (e.g., thinning hair, facial scarring, or a large nose), has many similarities to OCD (Phillips 1991). Patients with BDD experience obsessional thinking about the supposed defect and usually engage in associated repetitive ritualistic behaviors, such as mirror checking and reassurance seeking. BDD also appears similar to OCD in terms of age of onset, course of illness, and other variables (Phillips et al. 2006). Nonetheless, emerging data suggest that there are some important differences between the two disorders, and they are currently classified separately in DSM-IV-TR. Insight, for example, is more frequently impaired in BDD than in OCD. Furthermore, there is a greater prevalence of major depression, suicidality, and substance abuse in BDD (Phillips et al. 2006). If the content of a patient’s obsessions involves a concern about a supposed defect in appearance, BDD, rather than OCD, is the diagnosis that should be given.

**Obsessive–Compulsive Disorder Versus Obsessive–Compulsive Personality Disorder**

OCDP is a lifelong maladaptive personality style characterized by perfectionism, excessive attention to detail, indecisiveness, rigidity, excessive devotion to work, restricted affect, lack of generosity, and hoarding. OCD and OCDP have historically been considered variants of the same disorder on a continuum of severity, with OCD viewed as the more severe manifestation of illness. Contrary to this notion, studies using structured interviews to establish diagnosis have found that not all patients with OCD also have OCDP. One reason for the perception that these disorders are linked lies in the frequency of several OCDP traits in patients with OCD. In one study, the majority of 114 patients with OCD had perfectionism and indecisiveness (82 and 70, respectively). In contrast, other OCDP traits, such as restricted affect, excessive devotion to work, and rigidity, were seen infrequently.
Although perfectionism and indecisiveness are relatively common traits in patients with OCD, the distinction between OCD and OCPD is important, and several guidelines may be useful in distinguishing them. Unlike OCPD, OCD is characterized by distressing, time-consuming ego-dystonic obsessions and repetitive rituals aimed at diminishing the distress engendered by obsessional thinking. One of the hallmarks that traditionally has been used to distinguish OCD from OCPD is that, in contrast, OCPD features are considered ego syntonic. In addition, as previously noted, the traits of restricted affect, excessive devotion to work, and rigidity are generally characteristic of OCPD but not OCD. Although useful, these guidelines are not absolute, and some patients defy easy categorization. Some patients, for example, spend hours each day engaged in ego-syntonic behaviors such as excessive cleaning; such patients may seek treatment not because they are disturbed by their behaviors but because the behaviors cause problems in functioning or family friction. It is unclear whether some of these patients should be diagnosed with OCPD or subthreshold OCD.

**Obsessive–Compulsive Spectrum Disorders**

Certain disorders other than OCD—such as BDD, hypochondriasis, and eating disorders—are characterized by obsessional thinking and/or ritualistic behaviors. On the basis of these apparent similarities with OCD, the concept of OCD spectrum disorders has been developed. They have been defined as disorders that share features with OCD (Hollander et al. 2007) and are posited to have “spectrum membership” on the basis of their similarities with OCD across multiple domains. These domains include not only symptoms but also treatment response, comorbidity, joint familial loading, sex ratio, age at onset, course, premorbid personality characteristics, and presumed cause. Cause is inferred from characteristics such as neurological deficits, response to biological challenges, biochemical indices, brain imaging patterns (functional and anatomical), and environmental risk factors. It is worth noting that there are currently no operational criteria for what constitutes an OCD spectrum disorder; for example, in which of the preceding domains must similarities be documented, and how similar in each domain must the disorder be to OCD?

Disorders postulated to be OCD spectrum disorders include BDD, hypochondriasis, tic disorders, eating disorders, “grooming” disorders such as nail-biting and trichotillomania, and the impulse disorders (Hollander et al. 2007, see Figure 71–3). Of interest is a recent study investigating the frequency of these disorders in first-degree relatives of people with OCD. BDD, hypochondriasis, any eating disorder (although not anorexia or bulimia individually), and grooming disorders (but not the impulse control disorders) were found more frequently in probands with OCD than in general population controls. In addition, BDD and grooming disorders (although not the other disorders) were significantly more common in the first-degree relatives of OCD probands than in relatives of controls (reviewed in Hollander et al. 2007). This finding suggests that certain of the proposed OCD spectrum disorders may have a familial link to OCD. The relationship of these disorders with OCD is an area in which exciting research will be conducted in coming years.

**Differences in Gender Presentation**

Women appear to develop OCD slightly more frequently than do men. The BNPMs study reported a female-to-male ratio of 1.44:1 (Torres et al. 2006a). However, a study that assessed the presence of comorbid disorders characterized
by psychosis (schizophrenia, delusional disorder) or psychosis-like features (schizotypal personality disorder) in 475 patients with OCD found a different sex ratio. Fifty-six percent of the patients with OCD who did not have one of these comorbid disorders were women, whereas 85% of those with one of these comorbid disorders were men (Eisen and Rasmussen 1993).

A predominance of males has also been observed in child and adolescent OCD populations. In a study of 70 probands with OCD who were aged 6–18 years, 67% were males (Leonard et al. 1989). This finding may be due to the fact that males develop OCD at a younger age than do females. Evidence for sex differences in the genetic etiology of OCD have come from both a segregation analysis of a family sample (Nestadt et al. 2000b), as well as an association study of a polymorphism in the MAOA gene (Lochner et al. 2004).

**Etiology and Pathophysiology**

A number of intriguing avenues have been investigated to determine the etiology and pathophysiology of OCD. Although our understanding of what causes this disorder has continued to grow, there is still much to learn. It is likely that OCD is caused by a complex interaction of factors rather than a single defect. However, for the purpose of clarity, these factors are described separately.

**Genetic Factors**

**Twin and Family Studies**

A number of approaches have been used to evaluate the role of heredity in OCD. Twin studies have examined rates of concordant monozygotic twins versus discordant monozygotic twins with OCD. Although these studies have methodological limitations (e.g., a lack of a comparison group consisting of dizygotic twins), the data do support the notion that genetic factors are implicated in the etiology of OCD.

However, given that the concordance rate of less than 100% even in monozygotic twins, it is clear that environment also plays a role in the development of OCD. A recent review by van Grootheest et al. (2005) reported heritability estimates of OCD symptoms ranging from 27 to 47%.

A second approach to examining the role of genetics in OCD has been to investigate the rate of OCD in family members of OCD probands. In a recent review and meta-analysis of the genetic epidemiology of OCD, Hettema et al. (2001) analyzed four studies that met their stringent criteria of including (1) operationalized diagnostic criteria, (2) systematic ascertainment of probands and relatives, (3) direct interviews with the majority of subjects, (4) blind diagnostic assessment of relatives, and (5) inclusion of a comparison group. They reported an aggregate odds ratio of 4.0, supporting the familial aggregation of OCD.

Further evidence supporting familial transmission of OCD has been obtained by studying the frequency of OCD in relatives of patients with Gilles de la Tourette’s syndrome (TS). Family studies have found higher rates of OCD symptoms among family members of TS patients (Pauls et al. 1986) as well as higher rates of Tourette’s disorder and tics in first-degree relatives of children with OCD (Leonard et al. 1992). In addition, as previously noted, there are differences in the types of OCD symptoms seen in patients with TS plus OCD versus those with OCD alone. Moreover, it has been found that even among those OCD patients who do not have TS, if they share the TS/OCD symptom cluster (checking and ordering), they are more likely to have a positive family history for OCD (Pauls et al. 1986).

This may imply that there are distinct subtypes of OCD, some of which are familial and some of which are not. Taken together, available data support familial transmission in some cases of OCD and suggest that genetic factors play an important role in its etiology, particularly in patients with comorbid tic disorder.

**Linkage and Association Studies**

As with other complex diseases, it is unlikely that OCD is a single-gene disease. Association studies with candidate genes have focused mostly on the serotonin and dopamine systems, since medications treating OCD and TS are known to involve these systems. These genes have included the serotonin transporter, serotonin 1D, 2A, and 2C receptors, tryptophan hydroxylase, dopamine D2, D3, and D4 receptors, dopamine transporter, monoamine oxidase A, and catechol-o-methyltransferase. However, these studies have been equivocal, yielding positive as well as numerous negative results (Pato et al. 2002, Hemmings and Stein 2006).

A major drawback to candidate gene studies is that they require a considerably detailed understanding of the pathophysiology of the disease in question in order to generate candidate genes with substantive a priori support. As is the case with most psychiatric illnesses, the pathophysiology of OCD is poorly understood. Therefore, approaches based on gene discovery rather than the testing of candidates could be beneficial in identifying susceptibility genes as well uncovering previously unknown pathophysiological processes.

Linkage studies attempt to identify chromosomal regions where genetic markers cosegregate with the disease. The first genome-wide study implicated chromosome 9p24 (Hanna et al. 2002). A second study produced evidence supporting chromosomes 3q, 7p, 1q, 15q, and 6q (Shugart et al. 2006). The 9p24 linkage was followed up by testing the glutamate transporter gene, SLC1A1. This gene has now been positively associated in two independent samples (Dickel et al. 2006, Arnold et al. 2006).

In the last few years, genome-wide association has been heralded as a powerful means of discovering susceptibility alleles. This method tests hundreds of thousands of markers across the genome for association with the disease. This approach has yet to be implemented in OCD, but promises to overcome limitations of both linkage and candidate gene studies. Future directions in the genetics of OCD will also likely include whole-genome gene expression analysis using microarrays and analysis of copy number variation, as well as studies of epigenetic factors such as DNA methylation.

**Neurobiological Factors**

**Neuroanatomical Aspects**

Brain imaging techniques have advanced the search for abnormalities in brain function and/or structure in patients with OCD. Numerous studies have now been done with both structural imaging—CT (computed tomography) and MRI (magnetic resonance imaging) (Szeszko et al.
1999)—and functional imaging—PET (positron emission tomography), SPECT (single photon emission computed tomography), fMRI (functional magnetic resonance imaging), and MRS (magnetic resonance spectroscopy), and most recently, diffusion tensor imaging. These techniques have demonstrated abnormalities in OCD patients (Saxena et al. 1998). These abnormalities occur at rest and with symptom provocation (Baxter et al. 1992, Rauch et al. 1994), and they are “normalized” with effective treatment (Saxena et al. 2002, Nakao et al. 2005).

While not all results are in agreement, a majority of these studies have implicated abnormalities in the orbitofrontal cortex, anterior cingulate cortex, and structures of the basal ganglia and thalamus. These structures are proposed to be linked in neuroanatomical circuits (Baxter 1992). One well-articulated model by Saxena et al. (1998) proposes that OCD symptoms are mediated by hyperactivity in orbitofrontal–subcortical circuits, which might be due to an imbalance in tone between direct and indirect striato–pallidal pathways (Saxena et al. 1998, Lacerda et al. 2003, Szeszko et al. 2005) (see Figure 71–4). Some studies have implicated a preferential role for right anterolateral orbitofrontal cortex in both OCD symptoms and symptom response. This view has neurocognitive implications because studies of executive function in OCD patients have shown that patients have difficulty with alternation tasks and tasks that involve making choices (Cavedini et al. 2001), which may in fact be mediated by inappropriate activation of frontal striatal regions (Mulby et al. 2005). Successful treatment of OCD symptoms may lead to normalization of frontal cortical activation (Saxena et al. 2002, Nakao et al. 2005).

Further indirect evidence implicating a role for basal ganglia dysfunction in OCD lies in the clinical relationship between neurological insults to the basal ganglia and the subsequent development of obsessions and compulsions. There is an association between OCD and Tourette’s disorder, Sydenham’s chorea, bilateral necrosis of the globus pallidus, and postencephalitic parkinsonian symptoms.

**Neurochemical Aspects**

The hypothesis that OCD involves an abnormality in the serotonin neurotransmitter system has been called the serotonin hypothesis. Several different lines of investigation support this hypothesis: (1) therapeutic response of patients to chronic administration of certain types of medication, (2) measurements of central and peripheral neurotransmitter or metabolite concentration, and (3) pharmacologic challenge paradigms that measure behavioral and neuroendocrine effects produced by acute administration of selective pharmacologic agents, and (4) measurement of receptor binding using radioligands (reviewed by Mataix-Cols and van den Heuvel 2006, Westenberg et al. 2007).

All the evidence from treatment studies points to a role for serotonin and indicates a need for prolonged administration to see a positive effect. All of the antidepressants that effectively treat OCD affect serotonin (Westenberg et al. 2007). These antidepressants are potent inhibitors of the presynaptic reuptake of serotonin (i.e., SRIs). Those antidepressants that primarily affect the noradrenergic system have not been found to have antiossessional properties. Exactly how the SRIs improve OCD symptoms remains unclear; while the immediate action of these agents may be to increase serotonin in the synapse, they undoubtedly cause a cascade of changes, both presynaptically and postsynaptically. A number of studies have examined the relationship between SRI blood levels and improvement in OCD, with inconsistent results (reviewed by Westenberg et al. 2007).

**Figure 71–4**  Model of OCD pathophysiology: Imbalance of direct >> indirect pathway “tone” in orbitofrontal–subcortical circuit. Gpi, globus pallidus interna; SNr, substantia nigra. (Source: Saxena et al. 1998.)

Decreased levels of cerebrospinal 5-hydroxyindoleacetic acid, a serotonin metabolite that is reduced with serotonin reuptake inhibition, have been correlated with clinical improvement after clomipramine treatment. A decrease in platelet serotonin levels—an indirect measure of neuronal reuptake—has been highly correlated with clinical improvement with clomipramine (reviewed in Westenberg et al. 2007); higher whole-blood 5-HT levels have been associated with clinical improvement with SRIs (Delorme et al. 2004). These various studies generally support the association between improvement of OCD with an SRI and acute alterations of serotonin in the brain and, in turn, support the serotonin hypothesis.

More compelling have been recent in vivo studies quantifying the density of cerebral serotonin receptors as well as the serotonin transporter. Using the radioligand \(^{18}\)Faltanserin, Adams et al. (2005) reported increased density of serotonin 2A receptors in the caudate nuclei of OCD patient. This was interpreted as an upregulation of receptors in response to reduced synaptic concentrations of serotonin. Additionally, as revealed using SPECT, higher occupancy of the serotonin transporter by \([123\text{-}\beta]\) citalopram was associated with better citalopram response, further supporting the hypothesis (Stengler-Wenzke et al. 2006). These findings, however, have yet to be replicated. Furthermore, there is a relative paucity of such studies in OCD compared to, for example, Major Depressive Disorder. Additional methods such as postmortem brain studies, moreover, have yet to be employed in OCD.

Figure 71–5 shows a serotonin synapse with several of the possible sites of action for drugs that alter OCD symptoms.

**Figure 71–5**  Pharmacologic challenge studies constitute yet another line of evidence supporting the role of serotonin in the pathophysiology of OCD. The serotonin receptor partial agonist m-chlorophenylpiperazine, and more recently, the serotonin 1B agonist sumatriptan have been shown to increase symptoms of OCD and anxiety in patients with OCD but to have no effect in normal control subjects (Hollander et al. 2000).
The role of the dopamine system in OCD’s pathophysiology has also been investigated (reviewed by Mataix-Cols and van den Heuvel 2006). When added to the SRIs, dopamine antagonists (neuroleptic agents) decrease symptoms of OCD in patients with OCD and comorbid tics, as well as in patients with OCD and comorbid schizotypal personality disorder. More recently, the addition of low-dose antipsychotics as an augmentation strategy in treatment-refractory OCD has also been demonstrated to be successful in several double-blind, placebo-controlled studies (Bloch et al. 2006), and will be further discussed below. It has been hypothesized that some forms of OCD, particularly OCD plus Tourette’s disorder, may involve an imbalance in activity between serotonergic and dopaminergic systems (reviewed in Westenberg et al. 2007). Given the complex interactions and overlap among monoaminergic and other receptors in the brain, it is likely that a number of neurotransmitters are involved in OCD’s pathophysiology and etiology. Drawing from these rather conflicting results, Mataix-Cols and van den Heuvel (2006) describe the currently accepted pathophysiological model of OCD as involving two neuroanatomical pathways. A direct pathway involves an inhibitory GABAergic signal from the striatum to the internal part of the globus pallidus, which causes disinhibition of the thalamus, resulting in an excitatory effect on the prefrontal cortex. Additionally, an indirect pathway involves an excitatory signal to the internal part of the globus pallidus resulting from an inhibitory signal from the striatum to the external part of the globus pallidus and subthalamic nucleus. This in turn causes inhibition of the thalamus, and thereby, decreased excitation of the prefrontal cortex. The effects of long-term treatment with SRIs are probably several: to change the ratio of dopamine to serotonin turnover, alter the gene expression of target neurons to stress-related neuropeptides, and decrease the sensitivity of subtypes of presynaptic serotonin auto- and heteroreceptors belonging to the 5-HT<sub>1</sub> receptor family. Ongoing research is expected to elucidate further the likely role of serotonin and the possible role of other neurotransmitters in OCD.

**Animal Models**

Animal models may provide an important window on treatment efficacy and the influence of environmental and genetic factors in OCD. Because of the inherent difficulties in studying cognitive aspects of OCD (such as guilt, overresponsibility, and doubt) in animals, attention has focused on repetitive motor actions that are similar to compulsions. Ethologists have observed that when specific, goal-directed actions are thwarted, animals may substitute unrelated behaviors, known as displacement behaviors, which frequently involve digging, pecking, or grooming (Tinbergen 1953). These motor actions have several elements: they are triggered by conflict over territory or by frustration, they continue in a stereotyped fashion, and they are excessive and/or inappropriate to the context in which they are performed. Thus, they are similar to the compulsive behaviors

---

**Figure 71–5** Diagram of a serotonin (5-HT) synapse describing several of the possible sites of action for drugs that alter OCD symptoms. At (1) the rate-limiting step in serotonin synthesis, L-tryptophan (TRY) is hydroxylated to 5-hydroxytryptophan (5-HP). After serotonin is formed, it is sequestered into vesicles that are released at the presynaptic cell membrane (2). Fenfluramine increases this release. Once released, serotonin can interact with a number of different postsynaptic receptors (3). Several selective agonists (buspirone, m-chlorophenylpiperazine) have been developed to activate each of these serotonin receptor subtypes. Metergoline is a nonselective antagonist, blocking serotonin effects at each of these sites. The inactivation of serotonin is mediated by reuptake (4), the step inhibited by clomipramine, fluvoxamine, and fluoxetine. Finally (5), serotonin is either metabolized to its metabolite, 5-hydroxyindoleacetic acid (5-HIAA), by the enzyme monoamine oxidase (MAO), or recycled back into vesicles for release. (Source: Insel and Winslow 1990.)
of OCD and may also relate to compulsive grooming behaviors in BDD. Animal models offer the advantage of accessibility and ease of manipulation for controlled trials and as such can play a valuable role in understanding OCD’s etiology.

Most of the earlier animal models relied on such naturally occurring behaviors, called behavioral models, along with tail chasing, fur chewing, and weaving. As reviewed by Joel, the behavioral animal models currently in use comprise barbering and marble burying in mice, along with signal attenuation in mice, which was developed by Joel and colleagues (Joel 2006). The latter is based on the hypothesis that compulsive behaviors result from a deficit in the feedback associated with the performance of normal goal-directed responses. An example would include repetitive lever-pressing in mice in the absence of a conditioned stimulus, which would be analogous to compulsive behavior in humans. It has been shown that SSRIs, as well as D1-antagonists, may inhibit compulsion-like lever-pressing (Joel 2006). This may both validate the model as well as suggest a new treatment strategy for OCD (dopamine D1 receptor antagonism).

There are two additional types of animal models in OCD: those in which compulsion-like behaviors are induced by either genetic manipulations (genetic models) or pharmacological manipulations (pharmacological models). Examples of genetic models include the induction of excessive grooming by disruption of Hoxb8 (Greer and Capecchi 2002), a transcription factor involved in development; as well as “neat” repetitive chewing associated with knockout of the 5-HT2c receptor (Chou-Green et al. 2003). Examples of pharmacological models include “indecision” (i.e., a decrease in spontaneous alternation, or the tendency of rats to explore novel places sequentially) induced by 5-HT agonists (Yadin et al. 1991, Fernandez-Guasti et al. 2003), as well as “compulsive checking” (i.e., a short return time to certain locales) induced by the dopamine D2/D3 agonist quinpirole (Elam and Szechtman 2005, Szechtman et al. 1998).

**Psychological and Environmental Factors**

**Learning Theory**

A model based on the psychological concept of conditioning has been used to understand the development of obsessions and compulsions (Baer and Minichiello 1990). Compulsions, whether mental or observable, usually decrease the anxiety engendered by obsessional thoughts. Thus, if a person is preoccupied with fears of contamination from germs, repetitive hand washing usually decreases the anxiety caused by these fears. The compulsion becomes a conditioned response to anxiety. Because of the tension-reducing aspect of the compulsion, this learned behavior becomes reinforced and eventually fixed (Ruchman and Hodgson 1980). Compulsions, in turn, actually reinforce anxiety because they prevent habituation from occurring; that is, by performing a compulsion, contact with the fear-evoking stimulus (e.g., dirt) is not maintained, and habituation (a decrease in fear associated with the stimulus) does not occur. Thus, the vicious circle linking obsessions and compulsions is maintained (Figure 71–6). This learning theory model of OCD has had a major influence on the way behavioral therapy is used in its treatment.

**Psychoanalytic Theory**

Psychoanalytic theory is based on the concept that psychiatric symptoms have psychological meaning stemming from unconscious conflicts. In Freud’s theory, themes of control, aggression, and autonomy are dominant during the anal period of development, which occurs during toilet training. Poorly resolved childhood struggles over control can result in conflicts over obedience and defiance. The unconscious conflict between passivity and aggression, or obedience and defiance, may lead to anxiety. The anxiety produced by these conflicts is hypothesized to lead to the formation of obsessions and compulsions as well as the defenses of reaction formation, isolation, and undoing.

Much of the psychoanalytic literature on OCD does not distinguish between the phenomena observed in OCD (obsessions and compulsions) and the traits of OCPD (MacKinnon and Michels 1971). This distinction has relevance because of treatment implications. Although the clinical observations of earlier psychoanalysts, such as Freud’s famous Ratman case (Freud 1963), reflect current clinical presentations of Axis I OCD, understanding symptoms from the psychoanalytic perspective have not yielded improvement in this disorder’s symptoms. Conversely, characterologic problems such as perfectionism, indecisiveness, and rigidity, seen in OCPD, may benefit from a psychoanalytic orientation that focuses on the meaning of these symptoms or traits; such traits have typically not responded well to medications alone, although further investigation of this question is needed.

**Phylogenetic Model**

Recent theory has attempted to integrate the biology of OCD with psychological models by proposing a phylogenetic model based on systems theory. In this model, behavioral inhibition and harm-assessment systems, which develop early in human phylogeny, are disrupted. This disruption can occur at a hierarchically primary level of biological organization, resulting in neurobiologic disturbance, or at a hierarchically higher level of organization, leading to psychological disturbances. Such a model can help to explain the diversity of symptoms seen in OCD, from the more primitive biologically based behaviors based on fight/flight and risk to more psychologically sophisticated behaviors involving morality and guilt. This model might also explain why neither biological nor psychological treatments alone always lead to complete remission of symptoms (Cohen et al. 1997).

**Treatment Goals**

**General Considerations**

Both pharmacologic and behavioral therapies have proved effective for OCD. The majority of controlled treatment trials have been performed with adults aged 18–65 years. However, these therapies have been shown effective for patients...
of all ages. In general, children and the elderly tolerate most of these medications well. For children, lower doses are indicated because of lower body mass. For instance, the recommended dose for clomipramine in children is up to 150 mg/day (3 mg/kg/day) versus 250 mg/day in adults. Use of lower doses should also be considered in the elderly because their decreased ability to metabolize medications can increase the risk of side effects and toxicity (Pato and Zohar 2001). Behavioral therapy has also been used successfully in all age groups, although when treating children with this modality it is usually advisable to use a parent as a cotherapist. A flowchart that outlines treatment options for OCD is shown in Figure 71–7.

In general, the goals of treatment are to reduce the frequency and intensity of symptoms as much as possible and to minimize the amount of interference the symptoms cause. It should be noted that few patients experience a cure or complete remission of symptoms. Instead, OCD should be viewed as a chronic illness with a waxing and waning course. Symptoms are often worse during times of psychosocial stress. Even when on medication, individuals with OCD are often upset when they experience even a mild symptom exacerbation, anticipating that their symptoms will revert to their worst, which is rarely the case. Anticipating with the patient that stress may make the symptoms worse can often be helpful in long-term treatment. Expert consensus guidelines, based on completion of a survey by 79 experts in the field, provide a reasonable approach to clinical practice in treating patients with OCD. However, like any consensus report based on clinical practice, not all of the recommendations are supported by empirical data. Further work in neurosurgical techniques, particularly less invasive approaches like gamma knife and possibly transmagnetic stimulation, may offer other options in the future for treating OCD (Greenberg et al. 1997) (see later).

Somatic Treatments
The most extensively studied agents for OCD are medications that affect the serotonin system (see Figure 71–5). Many studies implicate the serotonin system in OCD’s pathophysiology, although comparative studies also seem to implicate other neurotransmitter systems, including

![Flowchart of treatment options for OCD](image)
the dopaminergic system, in treatment response (reviewed by Westenberg et al. 2007). The principal pharmacologic agents used to treat OCD are the SSRIs, which include clomipramine, fluoxetine, fluvoxamine, sertraline, paroxetine, and citalopram, and escitalopram.

Outcome measures in OCD treatment trials generally include the Yale–Brown Obsessive–Compulsive Scale (Y-BOCS; Goodman et al. 1989a, 1989b), a reliable and valid 10-item, 40-point semistructured instrument that assesses the severity of obsessions and rituals during the preceding week. Studies conducted since 1989 have generally used the Y-BOCS as one of the major outcome measures. Most studies have used Y-BOCS scores of 16–20 as a study entry criterion, although it has been argued that higher scores (e.g., 20–21) might reduce the increasing placebo response rates being obtained in OCD studies (Greist et al. 1995). Treatment response is generally considered to constitute at least a 25–35% reduction in OCD symptoms as measured by the Y-BOCS (Goodman et al. 1993). Another frequently used global outcome measure is the National Institute of Mental Health Global Obsessive–Compulsive Scale (NIMH-OC) (Pato et al. 1994) (Clinical Vignette 1).

### Clinical Vignette 1: Pharmacotherapy

Ms. M was a 38-year-old married teacher who had experienced OCD symptoms since age 10 years. At that time, she had a need to reread sentences, as well as a need to check things like doors and faucets to guard against something bad happening. Her symptoms subsided somewhat during her teenage years but resurfaced during her early 20s. She sought treatment from a hypnotherapist in her late 20s and subsequently did relatively well, with only minimal symptoms, for the next 10 years. She noted, however, that during that time she continued to be a nervous person who worried about everything.

At the time of her initial visit, she reported a significant worsening of her OCD symptoms during the previous weeks. In particular, she began to have trouble driving her car. She often found herself reeling her route to ascertain that she had not hit something or to pick up road debris that she was worried might get in her way. This behavior greatly lengthened her driving time and, as a result, Ms. M began to drive less and to avoid unnecessary trips like driving to stores to shop. As her symptoms worsened, she began to avoid driving at night because she worried that she would not see debris and other objects in the road. In addition, much to her chagrin, she began to involve her husband in her rituals by asking him to drive back with her to make sure that nothing was wrong. She also experienced increased checking behavior, for example, rechecking how she had written a check or retracing her steps at school to ascertain that she had not kicked something down the stairs. Overall, she estimated that her symptoms were moderately severe and taking about 3 hours per day. Ms. M had also begun to experience prominent neurovegetative symptoms of depression, including early morning awakening, decreased energy and initiative, psychomotor slowing, and a 10-pound weight loss.

Ms. M was entered in a 10-week placebo-controlled blinded clomipramine trial and received clomipramine 250 mg/day. Within 3 weeks of starting treatment, she began to show some signs of improvement. She reported less frequent episodes of driving back and less avoidance of driving to go shopping; however, she did not experience much change in other checking behaviors. After 5–6 weeks at 250 mg/day of clomipramine, Ms. M noted marked improvement (approximately 85%) in her symptoms. She had only transient episodes of needing to drive back, which lasted less than 5 minutes, and no avoidance of driving; her checking had also improved. She began to have some symptom-free days. Ms. M also had no depressive symptoms and experienced a general sense of well-being, which was a significant improvement from her baseline. However, she began to complain of significant drowsiness and fatigue, despite adequate sleep, as well as dry mouth and tremor.

Within 10 weeks of beginning treatment, Ms. M was virtually free of OCD symptoms, experiencing only a few mild and transient episodes. Because she was at the end of the blinded medication period, her clomipramine dose was decreased from 250 to 150 mg/day. Within 1 week, she reported that she had started retracing her route while driving and had other symptoms of OCD that occupied about 1 hour per day. Her dose was increased to 200 mg/day, but in 1 week she called her physician to say that she was distressed because her OCD symptoms had interfered with her ability to pick up her child and that her symptoms had increased to 3 hours per day. Her clomipramine was increased to 250 mg/day. Within 8 weeks, Ms. M had returned to her previous level of good health. She was driving normally, was not checking or engaging in avoidance behavior, and had no obsessional fear of harm coming to others. Although on some days she experienced about 45 minutes of fleeting symptoms, on other days she was totally symptom-free. However, she was experiencing some side effects, such as dry mouth, tremor, weight gain, and fatigue. Her fatigue became marked to the point that she came home from her job as a school teacher exhausted and slept 16 hours a day on the weekend.

After 1 year at 250 mg/day of clomipramine, a taper was again attempted, and the medication was discontinued within a month. Before the taper, Ms. M’s Y-BOCS score was 4 (out of a possible total score of 40), but after 2 weeks without medication it rose to 6, indicating an increased effort on her part to resist her obsessions and compulsions. After 7 weeks of not taking medication, her Y-BOCS score rose to 10, and after 15 weeks it rose to 16, indicating moderate symptom severity. She noted that she had 1–3 hours of obsessions and 1 hour of compulsions per day, with increasing effort needed to resist symptoms. In addition, she noted the return of her nervousness and tendency to worry. However, Ms. M also had a lessening of her fatigue and lost 5 of the 10 pounds she had gained on the medication.

The return of symptoms was distressing to Ms. M, and she decided to try another medication. Sertraline was begun, and after only 6–8 weeks of treatment, at 200 mg/day, she had a remission of all OCD symptoms and the return of a sense of well-being. She had no side effects. At 5 months of follow-up she remained symptom-free, and her Y-BOCS score had decreased to 1, with only 15 minutes of symptoms per week.

### Clomipramine

The tricyclic antidepressant clomipramine is among the most extensively studied pharmacological agents in OCD. This drug is unique among the anti obsessional agents in that, in
addition to its potency as an SRI, it has significant affinity for noradrenergic, dopaminergic, muscarinic, and histaminic receptors. The largest double-blind, placebo-controlled trial of clomipramine in OCD was conducted in a collaborative sample of 520 patients at 21 sites (The Clomipramine Collaborative Study Group 1991). Both outcome measures, the Y-BOCS and the NIMH-OC, demonstrated a significant decrease in the severity of OCD symptoms in the group receiving clomipramine compared to the placebo group. Duration of treatment was 10 weeks, and the mean dose was approximately 200 mg/day, with 69% of patients taking 150–250 mg/day. About half (51–60%) of the patients receiving clomipramine experienced a 35% or greater reduction in symptoms as measured by the Y-BOCS, whereas only 7–7.5% of the placebo group had a similar response. The most common side effects were those typical of the tricyclic antidepressants, including dry mouth, dizziness, tremor, fatigue, somnolence, constipation, nausea, increased sweating, headache, mental cloudiness, and sexual dysfunction. In a meta-analysis of seven double-blind, placebo-controlled trials, there was a net improvement of 8.19 in Y-BOCS scores in patients treated with clomipramine (Ackerman and Greenland 2002). In this analysis, clomipramine outperformed fluvoxamine, fluoxetine, and sertraline. Previous data have indicated that at doses of 300 mg/day or more, the risk of seizures is 2.1%, but at doses of 250 mg/day or less, the risk of seizures is low (0.48%) and comparable to that of other tricyclic antidepressants. It is therefore recommended that doses of 250 mg/day or less be used. Elderly patients may be more prone to tricyclic side effects, such as orthostatic hypotension, constipation (which may lead to fecal impaction), forgetfulness, and mental cloudiness, which might be confused with dementia. Most of these side effects can be treated by simply lowering the dose, although the cardiac conduction effects of tricyclic antidepressants may preclude the use of clomipramine in patients with preexisting cardiac conduction problems, especially atrioventricular block.

Several studies of IV clomipramine were promising as they demonstrated quicker onset of action and fewer side effects than the oral form, and it may be effective even in patients who do not respond to oral clomipramine. Oral clomipramine, like other SRIs, usually takes a minimum of 4–6 weeks to produce a clinically significant clinical response, but in at least one study by Koran et al. (1997), in which they used IV pulse dosing, patients showed a response within 4.5 days (Koran et al. 1997). The reasons for this unique response are not fully understood, but it is postulated that the IV preparation avoids first-pass hepatoenteric metabolism, leading to increased bioavailability of the parent compound clomipramine. This in turn may play a role in rapidly desensitizing serotonergic receptors or initiating changes in postsynaptic serotonergic neurons. However, in a recent randomized, double-blind, placebo-controlled double-dummy study by Koran et al., oral pulse-loading (simply giving these large doses orally rather than intravenously) of clomipramine resulted in a response that was equally rapid as that to the intravenous pulse-loaded formulation (Koran et al. 2006), but this has yet to be replicated. Although IV clomipramine for obsessional states has been studied as far back as 1973, this preparation is still not FDA-approved for clinical use in the US. Cardiac monitoring is recommended during the use of IV clomipramine.

Fluoxetine
Fluoxetine (as well as fluvoxamine, sertraline, paroxetine, and citalopram) is often referred to as a selective serotonin reuptake inhibitor (SSRI) and sometimes as serotonin transport inhibitor (STI) because they have a far more potent effect on serotonergic than on noradrenergic or other neurotransmitter systems. Despite their different chemical structures, all of the SSRIs appear to have similar efficacy in treating OCD (Denys 2006). Fluoxetine was first marketed in the US in 1987 for the treatment of depression, and was the first available SRI in this country. Initially, on the basis of fluoxetine’s selectivity for serotonin receptors, researchers were hopeful that this medication would be more efficacious than clomipramine, which has affinity for cholinergic, adrenergic, and histaminic receptors in addition to serotonergic ones. It has been demonstrated to be effective in three double-blind, placebo-controlled trials in a meta-analysis, demonstrating an improvement in Y-BOCS score of 1.6 points (Ackerman and Greenland 2002). Furthermore, it has been shown to be equally effective as clomipramine, although in meta-analysis the effect size of clomipramine was greater.

The fixed-dose trials of fluoxetine are particularly noteworthy (Tollefson et al. 1994a 1994b). Although these studies indicated that doses of 20, 40, and 60 mg/day were all effective when compared with placebo, there was a trend toward 60 mg/day being more effective. Some patients who did not respond at lower doses responded at higher doses, and others who responded at lower doses showed increased improvement at a higher dose (Tollefson et al. 1994a). In addition, patients maintained their improvement or experienced increased improvement during the 5- to 6-month follow-up period (Tollefson et al. 1994a). Another study reported that only a dose of 60 mg/day, and not less, was sufficient to prevent relapse at 1 year (Romano et al. 2001). Anecdotal clinical experience suggests that even larger doses, perhaps 80 mg/day and above, may be needed in some patients.

Fluoxetine has fewer side effects than clomipramine, reflecting its more selective mechanism of action. The most common side effects are headache, sexual dysfunction, nausea, insomnia, anorexia, dry mouth, somnolence, nervousness, tremor, and diarrhea. Side effects occur more frequently at higher doses (Tollefson et al. 1994b). Fluoxetine’s long half-life, which is unique among the SRIs, is 2–4 days for the parent compound and 4–16 days for its active metabolite (Pato et al. 1991a). This long half-life can be beneficial for patients who do not comply with treatment, because relatively high steady-state levels are maintained even when several doses are missed. However, the long half-life can present problems when switching or discontinuing fluoxetine, because 5 weeks or more may be required for the medication to be completely cleared from the body. Hence the added delay, 5 weeks rather than 2 weeks for the other SRIs, is required when switching from fluoxetine to an MAOI.

Fluvoxamine
Fluvoxamine became available for the treatment of OCD in the US in 1995. It is a unicyclic agent that differs from the other SSRIs in that it does not have an active metabolite. A meta-analysis of four double-blind, placebo-controlled trials demonstrated a net improvement in Y-BOCS score of 4.84
Sertraline
Sertraline is a naphthalenamine derivative with an active metabolite, n-desmethylsertraline. Meta-analysis of four double-blind, placebo-controlled studies, including one fixed-dose study of 325 patients, demonstrated that sertraline was significantly more effective than placebo, with efficacy similar to that of clomipramine (Ackerman and Greenland 2002). In the fixed-dose study, there was a trend toward 200 mg/day being more effective than 50 mg/day or 100 mg/day. Similar to other SSRI trials, the dropout rate from adverse side effects was only 10%. Typical side effects included nausea, sexual dysfunction, headache, diarrhea, insomnia, and dry mouth (Greist et al. 1995).

In patients with OCD and comorbid depression, sertraline was more effective for OCD symptoms than the non-SRI desipramine. Furthermore, even though desipramine did improve depressive symptoms, a significantly greater number of patients treated with sertraline achieved remission from depression (Hoehn-Saric et al. 2000). A more recent study compared sertraline to fluoxetine. Although these SRIs were similar in efficacy, sertraline was associated with earlier improvement and a possibly greater chance of remission (Bergeron et al. 2002).

Paroxetine
Paroxetine is another SSRI that differs in structure from those previously discussed. It is a phenylpiperidine compound that is marketed as an antidepressant and that, like sertraline, shows promise in the treatment of OCD. Its efficacy, as noted below, is comparable to that of other SRIs (Ackerman and Greenland 2002, Denys 2006). Side effects are similar to those of other SSRIs and include lethargy, dry mouth, nausea, insomnia, somnolence, tremor, sexual dysfunction, and decreased appetite. Reports of an acute discontinuation syndrome, which can include general malaise, asthenia, dizziness, vertigo, headache, myalgia, loss of appetite, nausea, diarrhea, and abdominal cramps, warrant a gradual reduction in dose if this medication is to be discontinued (reviewed in Baldwin et al. 2007).

Citalopram/Escitalopram
Citalopram is a cyclic phthalin derivative with S (active) and R (inactive) enantiomers; it is unique in its selectivity for serotonin reuptake compared to the other SRIs. It has few significant secondary binding properties, and its minimal effect on hepatic metabolism probably makes it safer to combine with other medications. A multicenter fixed-dose-placebo-controlled trial with 401 patients showed that 52–65% of patients responded in the three dosage groups compared to a 37% response rate in the placebo group. While there was a trend for a higher dose to lead to a higher response rate, as with other SRIs, there was no statistical difference between the three doses used (20, 40, and 60 mg/day). Typical side effects included fatigue, sweating, dry mouth, ejaculation failure, nausea, and insomnia, although many patients habituated to these side effects in 4–6 weeks. Thus, citalopram is a good choice for OCD treatment because of its side effect profile and low probability of causing drug–drug interactions (Richter 2001). At the current time, however, OCD remains an off-label indication for citalopram. Escitalopram, the more potent S enantiomer of citalopram, was introduced in 2001, and was initially FDA approved for the treatment of GAD. A recent randomized double-blind, placebo-controlled trial demonstrated that at the 20 mg dose, there were higher response and remission rates, improved functioning, and better tolerability than paroxetine (Stein et al. 2007).

Other Agents
Several open-label trials of venlafaxine suggest that this serotonin–norepinephrine reuptake inhibitor (SNRI) may be as effective as SRIs, but this has yet to be confirmed in double-blind, placebo-controlled trials (Denys 2006). Other agents that are potentially effective as monotherapy include aripiprazole, mirtazapine, and St. John's Wort (Hypericum perforatum) (reviewed in Denys 2006). However, these have also yet to be supported by double-blind, placebo-controlled studies. Although OCD is classified as an anxiety disorder, it tends to differ from the other anxiety disorders in that it has obsessions and compulsions as its hallmark, and these OCD symptoms usually require some regulation of serotonin to achieve symptomatic improvement. However, like other anxiety disorders, patient with OCD can have anxiety symptoms or comorbid panic attacks and may benefit from the addition of a benzodiazepine during the course of treatment.

Which SRI to Choose?
The efficacy of each SRI—clomipramine, fluoxetine, fluvoxamine, sertraline, paroxetine, citalopram, and escitalopram—is supported by existing data. During the last 10 years at least seven head-to-head SRI comparison studies have been done; six of which compared clomipramine to fluoxetine, fluvoxamine, paroxetine, or sertraline, and one study compared fluvoxamine to both paroxetine and citalopram (reviewed...
by Baer et al. 1990b, Ackerman and Greenland 2002, Denys 2006). In general, sample sizes have been small, usually with 10–30 patients per group. All of the studies found that the agents studied were equally efficacious, although they may have been underpowered to detect differences among medications.

However, several meta-analyses (Jenike et al. 1990, Greist et al. 1995, Greist and Jefferson 1998, Ackerman and Greenland 2002) of OCD trials, which compared SRIs across large placebo-controlled multicenter trials, lend some support to the notion that clomipramine might be more effective than the more selective agents. In a four-way (clomipramine, fluoxetine, fluvoxamine, and sertraline) meta-analysis, effect sizes were computed by comparing the average change in Y-BOCS scores pooled over various studies with different medications (Ackerman and Greenland 2002). Clomipramine led to the largest effect sizes. However, like most meta-analyses, these studies are flawed by factors that include variations in the study protocol, sample size, and the number of treatment-resistant and treatment-naive subjects. Nonetheless, as Greist et al. (1995) point out, these differences cannot explain the fact that the clomipramine trial had a lower dropout rate (12% overall) (Greist and Jefferson 1998, Greist et al. 1995) than other trials, despite a higher rate of side effects. In conclusion, these meta-analyses support a trial of clomipramine in all patients who do not respond to SRIs, even though clomipramine tends to cause more side effects and has greater toxicity in overdose.

A number of studies have assessed predictors of medication response. Predictors of poor response have included failure to respond to a previous SRI, early age of OCD onset, presence of schizotypal personality disorder, and the presence of hoarding and washing compulsions, as well as of religious and sexual obsessions. However, not all studies have had consistent findings, and more investigation of this issue is needed using larger and more narrowly defined samples (reviewed in Tukel et al. 2006).

It is worth noting that the SSRIs, via their effect on the liver cytochrome system enzymes, in particular CYP2D6, can inhibit the metabolism of certain other drugs. They can therefore elevate blood levels of a variety of coadministered drugs, including tricyclic antidepressants (such as clomipramine), carbamazepine, phenytoin, and trazodone. Although all SSRIs (with the exception of citalopram and escitalopram) share this property, fluoxetine may have the greatest effect (Liston et al. 2002). Some clinicians have taken advantage of these interactions by carefully combining fluvoxamine with clomipramine in order to block clomipramine’s metabolism to desmethylclomipramine; this in turn favors serotonin reuptake inhibition provided by the parent compound rather than the norepinephrine reuptake inhibition provided by the metabolite. However, caution should be used with this approach since the elevation in clomipramine levels, and perhaps other compounds, can be nonlinear and quickly lead to dangerous toxicity (Szegedi et al. 1996); at the very least, clomipramine levels should be carefully monitored and clomipramine must generally be used at much lower doses than usual when it is combined with an SRI.

All of the SSRIs are generally well tolerated, with a relatively low percentage of patients experiencing notable side effects or discontinuing them because of side effects. In addition, these compounds are unlikely to be lethal in overdose, except for clomipramine, which can lead to cardiac arrhythmias and death. All these agents can cause sexual side effects, ranging from anorgasmia to difficulty with ejaculatory function. However, such symptoms are not readily volunteered by the patient; thus it is important to ask. Should such symptoms be experienced, conservative measures may include dosage reduction, transient drug holidays for a special weekend or occasion, or switching to another SRI since patients may not have the same degree of dysfunction with a different agent. However, if the clinician feels that it is critical to continue the same agent, a number of treatments have been reported in the literature. Among those that have been tried are yohimbine, buspirone, cyproheptadine, bupropion, dextroamphetamine, methylphenidate, amantidine, nefazodone, and sildenafil, to name a few (reviewed by Taylor et al. 2005) (Clinical Vignette 1).

### Assessing Treatment Resistance

Before concluding that a patient is treatment resistant, the adequacy of previous treatment trials must be assessed (Table 71–2). In particular, it is critical to know both the duration and dose of every medication that has been used. Typically, patients who appear treatment resistant have received an inadequate duration of treatment, which should be a minimum of 10–12 weeks, or an inadequate medication dose, which should be the maximum dose for any particular agent. Some psychiatrists consider patients truly treatment resistant only if they have failed several adequate pharmacologic trials, including one with clomipramine, and several augmentation strategies including behavioral therapy. With this kind of aggressive treatment, the vast majority of patients usually experience some improvement, although few patients become symptom-free (Denys 2006).

When inadequate treatment is not the reason for poor treatment response, it is important to assess the accuracy of the diagnosis. Schizotypal personality disorder, borderline personality disorder, avoidant personality disorder, and OCPD seem to be associated with poorer response to

**Table 71–2** Things to Consider in Patients with Obsessive–Compulsive Disorder in Whom Initial Treatment Fails

**Assessing Treatment Resistance**

Before concluding that a patient is treatment resistant, the adequacy of previous treatment trials must be assessed (Table 71–2). In particular, it is critical to know both the duration and dose of every medication that has been used. Typically, patients who appear treatment resistant have received an inadequate duration of treatment, which should be a minimum of 10–12 weeks, or an inadequate medication dose, which should be the maximum dose for any particular agent. Some psychiatrists consider patients truly treatment resistant only if they have failed several adequate pharmacologic trials, including one with clomipramine, and several augmentation strategies including behavioral therapy. With this kind of aggressive treatment, the vast majority of patients usually experience some improvement, although few patients become symptom-free (Denys 2006).

When inadequate treatment is not the reason for poor treatment response, it is important to assess the accuracy of the diagnosis. Schizotypal personality disorder, borderline personality disorder, avoidant personality disorder, and OCPD seem to be associated with poorer response to...
pharmacotherapy; particularly if the personality disorder is the primary diagnosis (Jenike et al. 1986, Goodman et al. 1993).

As above, there is anecdotal evidence that up to 80 mg/day of fluoxetine is necessary for response in some patients. At the current time, there is only limited evidence suggesting that using doses higher than those recommended on package labeling are effective in the SRI treatment of OCD. Ninan et al. (2006) recently reported greater symptom improvement in patients receiving 250–400 mg/day sertraline compared to a 200 mg/day group in a multicenter double-blind trial. Systematic studies using other SRIs at doses higher than the maximum recommended by the pharmaceutical company have not been done to our knowledge. However, in our experience some patients benefit from higher doses but it must be done with strict monitoring and caution. Furthermore, there have been no studies supporting higher plasma levels as predictors of response. Switching agents from one SRI to another may be effective in some patients, but very few studies have examined this (reviewed in Denys 2006).

Behavioral therapy (see later) seems less effective in patients with comorbid major depressive disorder. Comorbid depression may inhibit the ability to learn and to habituate to anxiety. Initial pharmacotherapy sometimes improves depression, as well as OCD symptoms, and may increase the likelihood of success with behavioral treatment.

**Augmentation Strategies**

If a patient has had only a partial response to an antibesessional agent of adequate dose and duration, the next question is whether to change the SRI or add an augmenting agent. Current clinical practice suggests that if there is no response at all to an SRI, it may be best to change to another SRI. However, if there has been some response to treatment, an augmentation trial of at least 2–8 weeks may be warranted. The drug class with the greatest support as effective, augmenting agents are low-dose atypical antipsychotics. Nine double-blind, placebo-controlled trials of antipsychotic augmentation have recently been included in a meta-analysis (Bloch et al. 2006) that reported a lack of evidence of publication bias in published studies. This study reported that nearly a third of treatment-refractory OCD patients responded to this strategy, using a 35% reduction of Y-BOCS score as the definition of response. The agents with the most compelling evidence of efficacy were risperidone (three studies) and haloperidol (one study). The evidence for newer agents such as olanzapine and quetiapine was equivocal, necessitating additional studies of these agents. The results also suggest that given the good response to SSRIs alone, antipsychotic augmentation should be considered after a full trial of 3 months of an SSSI alone. Patients with comorbid tics were especially likely to respond. The use of an antipsychotic agent should be considered carefully in light of the risk of extrapyramidal symptoms and side effects such as weight gain, lethargy, and tardive dyskinesia. Thus, when a neuroleptic drug is used, target symptoms should be established before beginning treatment, and the medication discontinued within several months if target symptoms do not improve.

As reviewed by Denys (2006), augmenting agents that have been supported in at least one open-label trial have included morphine, the beta-blocker pindolol, venlafaxine, amitriptyline, the glutamate-modulating agent rituxol, and topiramate. The use of lithium (300–600 mg/day) and buspirone (up to 60 mg/day) as augmentation agents has also been explored. Both agents looked promising in open-label trials but failed to be effective in more systematic trials. Augmentation with fenfluramine (up to 60 mg/day), clonazepam (up to 5 mg/day), clonidine (0.1–0.6 mg/day), and trazodone (100–200 mg/day), as well as the combination of clomipramine with any of the SSRIs, has had anecdotal success but has not been evaluated in methodologically rigorous studies. Support for these agents remains modest at best, however, and they should clearly be considered second- or third-line alternatives.

**Behavioral Therapy**

Behavioral therapy is effective for OCD both as a primary treatment and as an SRI augmentation agent (Marks et al. 1988, Foa et al. 1985, Greist 1994, Neziroglu et al. 2006). This form of therapy is based on the principle of exposure and response prevention. The patient is asked to endure, in a graduated manner, the anxiety that a specific obsessional fear provokes while refraining from compulsions that allay that anxiety. The principles behind the efficacy of behavioral treatment are explained to the patient in the following way. Although compulsions, either covert or overt, usually immediately relieve anxiety, this is only a short-term solution; the anxiety will ultimately return, requiring the performance of another compulsion. However, if the patient resists the anxiety and urge to ritualize, the anxiety will eventually decrease on its own (i.e., habituation will occur), and the need to perform the ritual will eventually disappear. Thus, behavioral therapy helps the patient habituate to the anxiety and extinguish the compulsions.

Compulsions, especially overt behaviors like washing rituals, are more successfully treated by behavioral therapy than are obsessions alone or covert rituals like mental checking. This is because covert rituals are harder to physically resist than are rituals like hand washing and checking a door. In fact, washing rituals are the most amenable to behavioral treatment, followed by checking rituals and then mental rituals.

In the early stages of treatment, a behavioral assessment is performed. During this assessment, the content, frequency, duration, amount of interference and distress, and attempts to resist or ignore the obsessions and compulsions are catalogued. An attempt is made to clarify the types of symptoms, any triggers that bring on the obsessions and compulsions, and the amount and type of avoidance used to deal with the symptoms. For instance, in the clinical vignette described later, the fact that Ms. Z stopped preparing meals to deal with her obsessional concerns about contamination was carefully documented. The patient, usually with the help of a therapist, then develops a hierarchy of situations according to the amount of anxiety they provoke. During treatment, patients gradually engage in the anxiety-provoking situations included in their hierarchy without performing anxiety-reducing rituals (see Clinical Vignette 2).

Behavioral therapy can be used with patients of any age and has been used in young children, often with the help of a parent as a cotherapist. However, not many systematic
trials of behavioral treatment in children have been performed. More recently, behavioral therapy in a group setting has been explored and found as effective as, and perhaps even more effective than, individual behavioral treatment (Braga et al. 2005). The group seems to act as a catalyst for change by promoting group cohesion, support, and encouragement. Groups can include patients with different symptoms, though each has a personalized hierarchy. Because family members are often affected by the patient’s rituals and often function as unwilling participants in rituals, as members of the group, they not only gain knowledge and understanding about OCD but can be cotherapists at home for homework assignments.

Clinical Vignette 2: Behavioral Therapy

Ms. Z was a married woman in her late 20s whose primary OCD symptom consisted of severe contamination obsessions. She feared that she would contract cancer from various substances, such as detergents, chemical lawn treatments, foods, asbestos, gasoline, oil spills on beaches, and batteries. She also had aggressive obsessions that if she did not do certain things, harm would come to her family members. In response to these fears, Ms. Z washed more than 100 times per day, avoided situations that might lead to contamination, checked items repeatedly for evidence of contamination, and sought reassurance from others more than 50 times a day.

Ms. Z’s symptoms dated back to age 8 years when she had aggressive obsessions and felt that she had to touch certain things in her room. Her life had been riddled with magical thinking; to combat fears of dying or to prevent bad things from happening to others, she had to open and close the refrigerator in a certain way, had to close lids a certain way, had to touch the floor, and had to touch both of her eyes. She kept most of these rituals hidden from others.

Around the time she became pregnant in her late 20s, Ms. Z’s symptoms worsened. Her contamination fears heightened to the point that she avoided contact with family members and relatives who might be contaminated with cancer or contaminated because of where they lived. Her husband was drawn into her rituals, often giving her reassurance. She eventually stopped cooking because of her fears of insecticides, bacteria, and chemicals on food, and her son and husband ate meals at a relative’s house.

At initial evaluation, Ms. Z spoke of the distress and impairment she experienced from her symptoms and of her desire to stop her “strange” behavior. Ms. Z decided to pursue insight-oriented psychotherapy first for 6 months and only when this was not bringing improvement of her OCD symptoms did she finally agree to a more empirically established treatment for OCD, combined behavioral therapy and pharmacotherapy consisting of clomipramine, which was gradually increased from 50 to 250 mg/day. (Although it may appear obvious, it may be helpful to clarify that the clomipramine doses started low, perhaps 50 mg/day, and was raised gradually to 250 mg/day.)

Behavioral therapy was initially begun on an individual basis. During the first sessions, psychoeducation and exposure and response prevention techniques were discussed. One of the first homework assignments included keeping a daily record of how many times Ms. Z washed her hands. When she returned for the next session, she reported that the frequency had decreased; as she stated, “Knowing I had to write down when I had the urge prevented me from washing. Having to stop and think about why I was doing the ritual helped me to resist.” (In 10% of patients, record keeping alone results in a decrease in target behaviors.)

Sessions continued, with the therapist modeling exposure and response prevention. For example, the therapist asked Ms. Z to join her in touching doorknobs, floors, shoes, batteries, paint chips, and plant soil while continually reassuring her, identifying the cancer fear as OCD, and pushing her to understand that her initial urge to avoid or wash could easily become a command if she did not challenge the feeling. After every session, a specific homework assignment was negotiated that Ms. Z could practice daily. She was instructed to call the therapist if she had trouble with the homework assignments. Ms. Z reported compliance with homework assignments as well as a decrease in anxiety, but she continued to experience severe fear of contamination.

Ms. Z then entered a 10-session behavioral therapy group that strengthened her confidence and encouraged her to participate in group exercises (touching objects and resisting washing). By allowing her to share her experiences with other group members, the group also validated her feelings of frustration and isolation. Independently, Ms. Z began to choose goals such as allowing her son to have a toy that she had taken away because it was “contaminated,” resisting washing his hands, and making herself lunch for work.

However, it became apparent that as certain symptoms improved, Ms. Z continued to engage in many elaborate rituals at home. To address this problem, home visits were planned. While in the home, the therapist encouraged Ms. Z to touch and clean avoided articles of clothing, throw away rubber gloves that were used to prevent contamination, and even share feared contaminated foods like grapes and celery that Ms. Z had been avoiding because they could not be adequately washed or peeled.

Eventually, Ms. Z also enrolled with her husband in a second eight-session group behavioral treatment that included family members. This gave her husband the ability to observe participant modeling of exposure and response prevention with the support and validation of other family members.

During the next 18–24 months of treatment, Ms. Z began to set more challenging behavioral goals and decreased treatment from as many as three individual therapy sessions and two group and family behavioral group sessions per week to one individual behavioral session per week, with sustained improvement between sessions. She eventually contracted to cook meals, do laundry, and buy groceries and was able to have guests come to her house without experiencing excessive contamination concerns.

Despite its efficacy, behavioral therapy has limitations. To begin with, about 15–25% of patients refuse to engage in behavioral treatment initially or drop out early in treatment because it is so anxiety provoking (Greist 1994; see Figure 71–8). Behavioral treatment fails in another 25% of patients for a variety of other reasons (Greist 1994, Foa et al. 1983), including the following: concomitant depression; the use of central nervous system depressants, which may inhibit the ability to habituate to anxiety; lack of insight; poor compliance with homework, resulting in inadequate exposure; and poor compliance on the part of the therapist in enforcing
the behavioral paradigm (Greist 1994). Thus, overall, 50–70% of patients are helped by this form of therapy.

One of the issues that has emerged in treating OCD with CBT is the lack of trained therapists and the cost of repeated individual exposure sessions. Thus, in addition to developing group treatments, which allow therapists to treat a number of patients simultaneously, researchers have begun to develop computer-guided behavior therapy. Several recent reports have shown that while this modality is not as effective as individual behavior therapy, it does allow for significant improvement in symptoms over a control condition like relaxation therapy (Greist et al. 2002). In our clinical experience such treatment is more suitable for patients whose illness is less severe and less complex (e.g., without problems of comorbidity).

Behavioral therapy can be used as the sole treatment of OCD; particularly with patients whose contamination fears or somatic obsessions make them resistant to taking medications. Behavioral treatment is also a powerful adjunct to pharmacotherapy. A meta-analysis has demonstrated that combined behavioral therapy and SRI treatment is superior to either behavioral therapy or pharmacotherapy alone (Eddy et al. 2004). From a clinical perspective, it may be useful to have patients begin treatment with medication to reduce the intensity of their symptoms or comorbid depressive symptoms if present; patients may then be more amenable to participating in behavioral therapy and experiencing the anxiety that will be evoked by the behavioral challenges they perform (see Chapter 91 for further discussion).

Work by Baxter et al. (1992) has illustrated some interesting correlations between treatment response and changes in neurophysiology. These investigators studied two groups of nine patients each, with one group treated with medication only (fluoxetine up to 80 mg/day for 10 weeks) and the other group treated with individual behavioral therapy only (exposure and response prevention for 10 weeks). Positron emission tomography scans with $^{18}$F-fluorodeoxyglucose were performed on all patients before and after treatment. Compared with nonresponders and control subjects, responders in both the medication and the behavioral treatment groups showed a decrease in activity in the right head of the caudate nucleus. This finding seems to support the notion that both forms of treatment bring about similar changes in neurophysiology, which lead to improvement in symptoms. These results also provide important theoretical links with the serotonin hypothesis described earlier in this chapter, as basal ganglion structures like the caudate nucleus have been postulated to mediate serotonin function.

**Other types of Psychotherapy**

The use of psychotherapeutic techniques of either a psychoanalytic or a supportive nature has not been proved successful in treating the specific obsessions and compulsions that are a hallmark of OCD. However, the more characterological aspects that are part of OCPD may potentially be helped by a more psychoanalytically oriented approach. As noted earlier, the defense mechanisms of reaction formation, isolation, and undoing, as well as a pervasive sense of doubt and need to be in control, are hallmarks of the obsessive–compulsive character. Salzman (1983) and MacKinnon and Michels (1971) have written elegantly on how to approach the maladaptive aspects of this character style in therapy. In essence, the patient must be encouraged to take risks and learn to feel comfortable with, or at least less anxious about, making mistakes and to accept anxiety as a natural and normal part of human experience. Techniques for meeting such goals in treatment may include the psychiatrist’s being relatively active in therapy to ensure that the patient focuses on the present rather than getting lost in perfectly recounting the past, as well as the psychiatrist’s being willing to take risks and present herself or himself as less than perfect.

**Neurosurgery**

Occasionally, even after receiving adequate pharmacotherapy (including augmentation), adequate behavioral therapy, and a combination of behavioral therapy and pharmacotherapy, patients may still experience intractable OCD symptoms. Such patients may be candidates for neurosurgery. Although criteria for who should receive neurosurgery vary, it has been suggested that failure to respond to at least 5 years of systematic and clearly adequate treatment is a reasonable criterion. Frequently used criteria are the following: a minimum of two adequate medication trials with augmentation plus adequate behavioral therapy in the absence of severe personality disorder.

The procedures that have been most successful interrupt tracts involved in the serotonin system. The surgical procedures used—anterical capsulotomy, cingulotomy, and limbic leukotomy—all aim to interrupt the connection between the cortex and the basal ganglia and related structures. Current stereotactic surgical techniques involve the creation of precise lesions, which are often only 10–20 mm, to specific tracts. These procedures have often been done with radio-frequency heated electrodes and more recently with gamma knife techniques. Postsurgical risks have been minimized, and in some cases cognitive function and personality traits improve along with symptoms of OCD.

Data compiled from a number of small studies have yielded success rates of 25–84% after cingulotomy (Cosgrove and Rauch 2003). However, most samples are small and the procedures have often differed in both lesion location and size, making it difficult to compare them. However, in a
recent prospective long-term follow-up study, all 44 patients received the same procedure (cingulotomy), although some had single procedures and others multiple procedures (Dougherty et al., reviewed in Cosgrove and Rauch 2003). This study had several important findings. Clinical improvement occurred in 32–45% of patients, depending on the criteria used to rate full or partial response, and the average effect size was 1.27, comparable to that seen in pharmacologic trials (1.09–1.53). However, these changes were not immediately apparent postoperatively, and most patients were encouraged to engage in pharmacotherapy and/or behavior therapy postoperatively. The longitudinal follow-up component of the study, which was a mean duration of 32 months, allowed the researchers to assess the longer term impact of the procedure in ways other studies could not. Of particular note, patients continued to show improvement for up to 29 months after surgery without receiving further procedures. As a result, the authors noted that the typical 6-month wait before deciding whether to repeat and extend the lesion may be too brief. A recent study reported a 48% mean improvement rate in the Y-BOCS, as well as no significant incidence of adverse events in Korean patients followed for up to 24 months (Jung et al. 2006).

Deep brain stimulation, which involves stimulation with an electrical current at sites deep in the brain rather than on the surface, is a more recent technique that is currently under investigation. Neurosurgical teams in the US and Europe have studied deep brain stimulation (DBS) of the ventral anterior limb of the internal capsule and adjacent ventral striatum (VC/VS) for severe and highly treatment-resistant obsessive–compulsive disorder (OCD). Long-term data show that the procedure can be successfully implemented by dedicated interdisciplinary teams, and support its therapeutic promise (Greenberg et al. 2006). In conclusion, neurosurgical treatments offer hope to some of the most severely ill and treatment-resistant patients and should therefore be considered. However, which surgical lesions are most effective in which patients still needs much more study (see other chapters for further discussion).

Issues in the Physician–Patient Relationship
Treatment for OCD is often effective, leading to at least some response in a majority of patients. However, treatment adherence is difficult for some patients, which may interfere with treatment efficacy. Short- and long-term compliance with treatment can be greatly facilitated by considering how the nature of the illness affects the treatment modalities used.

At the core of OCD are the concepts of obsessional doubt, risk aversion, and a need to feel in control of one’s environment. These three concepts affect behavioral and pharmacological treatment. In the initial phases of behavioral treatment, it may be difficult to engage the patient in treatment because of his or her doubt that the treatment will be effective and an unwillingness to experience the anxiety that results from exposure to feared stimuli. Extra time often must be spent convincing patients of the potential efficacy of treatment and lack of serious side effects from behavioral treatment. Unlike pharmacological treatment, in which the side effects can be quantified in medical terms, the side effects that patients fear from behavioral treatment are related to their cognitive distortions. For instance, those with contamination fears may be thoroughly convinced that simply walking by an AIDS clinic will put them at risk of contracting AIDS or that simply using a public bathroom will give them a communicable disease. Thus, reassurance that this is not the case and that it is safe to engage in behavioral treatment may first involve playing out the catastrophic consequences in their mind or role-playing and discussing the irrational nature of the fear to the fullest extent possible.

When behavioral treatment is started, it is customary to develop a hierarchy of subjective units of distress, which rate particular events according to how much anxiety they produce. For some patients, the ability to develop this hierarchy and thereby obtain a sense of control over their fears, and the ability to begin with the least stressful challenges, can allow them to engage in behavioral treatment. Emphasizing that the patient and therapist are a team and that the patient and therapist will design exposures together may be helpful.

Similar concerns related to doubt, risk aversion, and control must also be addressed when pharmacological treatment is undertaken. In the initial treatment phases, the major task is getting the patient to engage in treatment. Patients with OCD, particularly those with contamination and somatic obsessions, often have numerous questions about medication safety and may be hesitant to take them. Patients with contamination and somatic obsessions may be more likely to engage in behavioral treatment initially.

Although it is important that patients have a thorough understanding of side effects, the psychiatrist should not be thorough to an obsessional degree. Many patients with OCD want a detailed understanding of every side effect and have difficulty differentiating which side effects are of concern and which are not. Thus, it is critical when discussing side effects to present an objective assessment of the relative frequency and severity of various side effects. It is important to emphasize that even though some of the rare side effects are more serious than the more common side effects, they are unlikely to occur. It is also worth keeping in mind that the patient’s concerns about a particular side effect may be different from the psychiatrist’s. Again, it may help to elicit the catastrophic fears that the patient has and address the irrational obsessional qualities of those fears.

The initial phase of treatment is often the most difficult. This has to do with both risk aversion and a need to be in control. With pharmacologic treatment, patients may occasionally experience an initial worsening of symptoms in addition to side effects. This can be terrifying to the patient and can lead to an abrupt discontinuation of the medication. Warning the patient before treatment that this might occur increases the patient’s sense of control. Similarly, the antidepressant effects of treatment often take 6–10 weeks to be seen and are often gradual in onset. This gradual response is often delayed until after the patient experiences some side effects. Thus, the early phase of treatment may need to focus on encouraging the patient to stay on medication despite side effects and no improvement. Side effects can often be framed as a good sign that the medication is being actively absorbed by the body. Again, preparing patients in advance helps them feel in control and able to continue treatment. The gradual onset of improvement, although in some cases
frustrating, is also reassuring to patients who might feel out of control if improvement occurred too rapidly.

Unlike many patients with mood disorders, most patients with OCD do not have full recovery from their symptoms. Although the majority of patients, perhaps as many as 85%, experience some improvement, most tend to remain symptomatic to some degree (The Clomipramine Collaborative Study Group 1991), and even if treated with CBT and medications, when followed for up to 8 years (Ruder et al. 2005). Nonetheless, symptom improvement of even 10–15% can have a dramatic positive effect on their lives.

Duration and Discontinuation of Treatment
Little systematic research has been performed to guide decisions about continuation, maintenance, and discontinuation of treatment. The largest study of extended pharmacologic treatment involved fluoxetine (Tollefson et al. 1994b). In this study, 70 patients who had responded to fluoxetine and 198 patients who had not responded during an acute 13-week trial were given the opportunity to continue on medication for another 6 months. At the end of the 6 months, 74.3% of those who had responded initially experienced further improvement. In the nonresponder group, 91.7% experienced a decrease in symptoms when the medication dose was increased from the previous unsuccessful dose. Only 19% of patients (N = 13) experienced a significant worsening of symptoms during the follow-up period. Similar to previous reports on fluoxetine, this study suggested that symptom improvement was maintained over time. Even more important, further improvement occurred in responders with longer treatment and in nonresponders with continued treatment at higher doses.

In another study, 85 patients who had been treated with a variety of antidepressional medications were followed up 1–3.5 years after initial treatment (Orloff et al. 1994). Ninety-four percent of the patients were still taking medication, and 87% had maintained previous gains or achieved further improvement. Thus, from a clinical point of view, it seems wise to continue medication for an extended period, perhaps for 6 months to a year after initiating treatment, because during this period improvement is maintained and some patients experience further improvement. Overall, this extended duration of treatment did not result in worsening side effects; in fact, in most cases patients habituated to side effects. In general, the most bothersome side effects that persist with SRI treatment appear to be fatigue, weight gain, and sexual dysfunction.

In recent years a number of studies of long-term efficacy have emerged. One study that included a follow-up period of 2 years for 38 OCD patients on sertraline showed continued efficacy with fewer side effects with longer term treatment (Rasmussen et al. 1997). Other studies have attempted to answer important clinical questions not only about long-term efficacy but also about the effects of medication discontinuation after 1 year of treatment (Kordon et al. 2005). The latter is an important question because few studies of systematic discontinuation have been done, and in those that have been done relapse rates were quite high, above 90% (Pato et al. 1988, Leonard et al. 1991). One such study (Koran et al. 2002) involved 223 patients who had been successfully treated with single-blind sertraline for 52 weeks who were then randomized in a double-blind manner to continue treatment for another 6 months or placebo. One-third of the patients in the placebo group relapsed; this was surprisingly lower than the percentage found in earlier studies. The authors offered several plausible explanations for this, which included the possibility that 1 year of effective treatment may provide sustained benefit for patients, and that patients may have engaged in self-directed behavior therapy, something that was not readily available at the time of the previous discontinuation studies. They also noted that while OCD symptom ratings did not worsen in the placebo-treated group as a whole, quality of life did significantly deteriorate. This finding points to the need for more sensitive measures of patient improvement and for further studies of long-term treatment efficacy.

Some preliminary data have suggested that in treatment responders it may be possible to decrease the dose of clomipramine over the longer term without subsequent relapse (Pato et al. 1990). Two studies have more systematically addressed this issue. In one study (Mundo et al. 1997), patients were treated with one-third or two-thirds of their effective doses of clomipramine or fluvoxamine, without experience a worsening of symptoms over 102 days. In another study (Ravizza et al. 1996), doses of clomipramine, fluoxetine, or fluvoxamine were halved, without worsening of symptoms over the next 3 months. Thus it may be possible to decrease the SRI dose in longer term treatment, although this important issue needs further investigation.

The data on discontinuation of behavioral therapy are also encouraging. In summarizing data from several 1- to 6-year follow-up studies of behavioral therapy, O’Sullivan and Marks (1991) noted that overall about 75% of patients continued to do well at follow-up. However, most studies also noted that few patients were symptom-free. A recent study followed up 102 patients who had received fluvoxamine with or without CBT (defined as either cognitive therapy or exposure in vivo with response prevention) for 5 years. Fifty-four percent of patients no longer met criteria for OCD. Furthermore, the type of treatment received did not predict patient outcome (van Oppen et al. 2005).

Conclusion
For many patients with OCD the illness is lifelong, starting in early childhood and extending into adulthood. It is often familial and accompanied by comorbid conditions including, depression, other anxiety disorders, Tourette’s syndrome and even psychosis. However, with a combination of pharmacologic and behavioral treatment, at adequate dose and duration, patients can often have significant improvement in symptoms and overall function.

Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria
The ICD-10 Diagnostic Criteria for Research for Obsessive–Compulsive Disorder differentiate between obsessions and compulsions based on whether they are thoughts, ideas, or images (obsessions) or acts (compulsions). In contrast, DSM-IV-TR distinguishes between obsessions and compulsions based on whether the thought, idea, or image causes anxiety or distress or prevents or reduces it. Thus, in DSM-IV-TR, there can be cognitive compulsions that would be considered obsessions in ICD-10. In addition, ICD-10 sets a
minimum duration of at least 2 weeks whereas DSM-IV-TR has no minimum duration.

Chapter 71 • Anxiety Disorders: Obsessive–Compulsive Disorder 1469

This chapter reviews posttraumatic stress disorder (PTSD) and the relatively new diagnosis of acute stress disorder (ASD). We provide definitions and summarize epidemiology, etiology, pathophysiology, diagnosis, differential diagnosis, and comorbidity. We also review the course and natural history of these disorders. Finally, we review overall goals of treatment and discuss specific treatment approaches and factors influencing response.

POSTTRAUMATIC STRESS DISORDER

Diagnosis

Definition and Diagnostic Features

PTSD is defined in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) by six different criteria (American Psychiatric Association 2000). First, the disorder arises in a person who has been exposed to a traumatic event in which he or she experienced, witnessed, or was confronted with actual or threatened death or serious injury or a threat to the physical integrity of self or others. A wide range of traumatic events may meet this criteria, including military combat exposure; natural disasters; serious accidents; childhood physical, sexual, or emotional abuse; adult physical and sexual assault; domestic violence; and terrorist incidents. Furthermore, the emotional response to this traumatic event must have involved intense fear, helplessness, or horror. In children, the response may take the form of disorganized or agitated behavior.

Second, there must have been at least one of five possible intrusive symptoms focused on the reexperiencing or recollection of the trauma. The first includes distressing recollections, images, thoughts, or perceptions of the traumatic event. For instance, a rape survivor may have disturbing recollections of details of the assault that come to mind unexpectedly when she does not expect to think about the event; these memories may evoke similar feelings of fear and helplessness as when the event occurred. A second reexperiencing symptom may include recurrent distressing nightmares, where trauma survivors may struggle at night reliving the trauma in their dreams. Third, trauma survivors may act or feel as if the trauma were recurring, also known as “flashbacks.” These are very vivid reliving experiences in which they may have sensory experiences, including sights, sounds, and smells, related to the trauma. Fourth, trauma survivors may have intense psychological distress when exposed to internal or external cues resembling the trauma (e.g., rape survivor acutely distressed when seeing a man that looks like the perpetrator). The last intrusive symptom includes physiological reactivity (e.g., increased heart rate (HR) and sweating) when exposed to trauma-related cues. Allowance is made for a different set of reactions in children, in whom reexperiencing symptoms may take the form of repetitive play, frightening dreams without recognizable content, or reenactment of the trauma.

Third, persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness must occur as evidenced by at least three out of seven symptoms. Although grouped together as one criterion, it is likely that phobic avoidance, emotional numbing, and withdrawal do not reflect the same underlying phenomenon. These seven symptoms include avoidance of thoughts, feelings,
or conversations about the trauma; avoidance of activities, places, or people that cause remembrance of the trauma; difficulty recalling important details of the traumatic stressor; decreased interest in significant life activities; feeling detached or distant from others; a restricted range of affect; and sense of a foreshortened future.

Fourth, there must be at least two out of five symptoms of increased arousal following exposure to the traumatic event. Arousal symptoms may include sleep disruption, irritability or anger outbursts, problems concentrating, hypervigilance, and exaggerated startle responses. Diagnostically, all of these symptoms should have an onset temporally related to the traumatic event.

Symptoms of PTSD should last at least 1 month, and it is necessary that the symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. PTSD is considered to be “acute” if the duration of symptoms is between 1 and 3 months or “chronic” if the symptoms persist for 3 months or longer. If symptoms do not occur until at least 6 months have passed since the stressor occurred, the delayed onset subtype is given. Please refer to the above table which outlines

or conversations about the trauma; avoidance of activities, places, or people that cause remembrance of the trauma; difficulty recalling important details of the traumatic stressor; decreased interest in significant life activities; feeling detached or distant from others; a restricted range of affect; and sense of a foreshortened future.

Fourth, there must be at least two out of five symptoms of increased arousal following exposure to the traumatic event. Arousal symptoms may include sleep disruption, irritability or anger outbursts, problems concentrating, hypervigilance, and exaggerated startle responses. Diagnostically, all of these symptoms should have an onset temporally related to the traumatic event.

Symptoms of PTSD should last at least 1 month, and it is necessary that the symptoms cause clinically significant distress or impairment in social, occupational, or other areas of functioning. PTSD is considered to be “acute” if the duration of symptoms is between 1 and 3 months or “chronic” if the symptoms persist for 3 months or longer. If symptoms do not occur until at least 6 months have passed since the stressor occurred, the delayed onset subtype is given. Please refer to the above table which outlines
the specific DSM-IV-TR PTSD symptomatology and Figure 72–1 for a PTSD diagnostic decision tree.

**Assessment**

PTSD assessment experts have suggested that the comprehensive evaluation of PTSD should include information from the traumatized individual, collaterals, and psychometric indices, such as self-report questionnaires and personality assessment (Wilson and Keane 2004). The standard for diagnosis in clinical research studies is always to use a structured clinical interview. The administration of self-report instruments can be used to corroborate information obtained in the clinical interview or can be used as a screening assessment prior to a clinical interview. All information would then be integrated on the basis of clinical judgment, especially if discrepancies existed. A number of structured interviews and self-rating scales are available. The “gold standard” of structured clinical interviews is the Clinician-Administered PTSD Scale (CAPS; Blake et al. 1990). Other instruments that have been used to evaluate PTSD are the Structured Clinical Interview for DSM-IV-TR (First et al. 1996), the Diagnostic Interview Schedule (Robins et al. 1981), and the Structured Interview for PTSD (Davidson et al. 1989). Self-rated measures include the Davidson Trauma Scale (Davidson et al. 1997), the Short PTSD Rating Instrument (Connor and Davidson ), the PTSD Checklist (Weathers et al. 1979), the PK scale on the Minnesota Multiphasic Personality Inventory (Keane et al. 1984), the Mississippi Scale for Combat-Related PTSD (Keane et al. 1988), the Impact of Events Scale (Horowitz et al. 1979), and the PTSD Scale (Foa et al. 1993, 1995).

Similar to adult assessment, a comprehensive evaluation of PTSD in children and adolescents should include direct observation, structured interview, self-report measures, collateral informants (e.g., parent and teacher reports), and behavioral analysis of pre- and posttrauma functioning. Structured interviews and psychometric measures are available for children with PTSD but are less well developed with regard to having established validity and reliability data (Stallings and March 1995). Nader et al. (1994), for instance, have developed a version of the CAPS for children and adolescents. This scale allows for current and lifetime diagnoses.
as well as the dimensional assessment of PTSD symptoms and related psychopathology. It has also been suggested (Costello 1989) that the use of additional measures such as the Conners Parent Rating Scale and Conners Teacher Rating Scale (Conners 1985) are important adjuncts to assess externalizing comorbid symptoms, whereas the Children’s Depression Inventory (Kovacs 1985) can be used to assess internalizing symptoms found in PTSD.

**Epidemiology**

Community-based studies conducted in the United States have documented a lifetime prevalence rate for PTSD of approximately 6.8–8.0% of the adult population (Kessler et al. 1995, 2005). General population female-to-male lifetime prevalence ratio is 2:1 (Breslau 2001). General population prevalence rates from other countries indicate variation based on levels of economic development (Keane et al. 2006); that is, PTSD prevalence tends to be higher in less economically developed, non-Western countries, with reported ranges from 1.5% in an Australian sample to 37.4% in an Algerian sample (Keane et al. 2006). The highest rates of PTSD occurrence associated with particular traumatic exposures (i.e., occurring in one third to three fourths of those exposed) are among survivors of rape, those exposed to military combat and captivity, those involved in graves registration (i.e., registering dead bodies through the morgue), and survivors of ethnically or politically motivated internment and genocide (Breslau 2001).

Epidemiological studies show that PTSD often remains chronic, with a significant number of people remaining symptomatic several years after the initial event. In support of this view are epidemiological data that show that recovery frequently does not occur. For example, the National Vietnam Veterans Readjustment Study (Kulka et al. 1990) found lifetime and current prevalence rates of PTSD to be, respectively, 30.9 and 15.2%. These data have recently been reanalyzed using more stringent inclusion criteria (Dohrenwend et al. 2006) and suggest slightly more conservative lifetime and current prevalence rates of 18.7 and 9.1%. However, this study is controversial and some experts suggest this may underestimate the actual prevalence rates among Vietnam veterans. In a nationally representative sample of rape victims, Kilpatrick et al. (1992) found a lifetime prevalence rate of 32% and a current prevalence rate of 12%. In children, studies by Pynoos et al. (1987, 1993) revealed prevalence rates of 58.4% in children exposed to sniper attacks in the United States and 70.2% in those exposed to an earthquake in Armenia. In two of the epidemiological catchment area (ECA) sites, Davidson et al. (1991) and Helzer et al. (1987) found that 47 and 33%, respectively, retained the diagnosis of PTSD for more than 1 year. Kessler et al. (1995) documented that one third of those diagnosed with PTSD fail to recover even after many years. Therefore, chronicity of PTSD is not limited to the more severe treatment-seeking samples.

**Comorbidity Patterns**

The wealth of clinical literature describes the complexity of PTSD and the fact that PTSD is unlikely to occur in isolation. Psychiatric comorbidity is the rule rather than the exception, and a number of studies have demonstrated this in both clinical and epidemiological populations (e.g., Davidson et al. 1985, 1991, Kessler et al. 1995). In these studies, a wide range of disorders is likely to occur at an increased probability. These include major depressive disorder, all of the anxiety disorders, alcohol and other substance use disorders, somatization disorder, and schizophrenia and schizophréniform disorder. A few studies have documented the course of comorbid conditions. For example, Shalev et al. (1990) have shown that major depressive disorder co-occurs with PTSD, but can take a separate course. Several researchers have provided evidence that comorbid substance abuse tends to be a consequence rather than a precursor of PTSD (Bremner et al. 1996, Breslau et al. 1991).

**Course**

Immediately following traumatic exposure, a high percentage of individuals develop a mixed symptom picture, which includes disorganized behavior, dissociative symptoms, psychomotor change, and sometimes, paranoia. The diagnosis of ASD, as described later in this chapter, accounts for many of these reactions (American Psychiatric Association 2000). These reactions are generally short lived, although by 1 month the symptom picture often settles into a more classic PTSD presentation, such that after rape; for example, as many as 90% of individuals may qualify for the diagnosis of PTSD. Approximately 50% of people with PTSD recover, and approximately 50% develop a persistent, chronic form of the illness still present 1 year following the traumatic event. The longitudinal course of PTSD is variable (Davidson et al. 2004) in both child and adult samples. Permanent recovery occurs in some people, whereas others show a relatively unchanging course with only mild fluctuation. Still others show a more obvious fluctuation with intermittent periods of well-being and recurrences of major symptoms. In a limited number of cases, the passage of time does not bring a resolution of symptoms, and the patient’s condition tends to deteriorate with age. Particular symptoms that have been noted to increase with time in many people include startle response, nightmares, irritability, and depression. One recent longitudinal study (Solomon and Mikulincer 2006) highlighted this variable course of PTSD among veterans over a 20-year period. They assessed Israeli soldiers who fought in the Lebanon War at 1, 2, 3, and 20 years after combat and discovered that many of the participants displayed temporal differences in their symptom profiles, with reactivation of symptoms and relapse occurring frequently and the lowest rate of symptom endorsement at the third time point. They speculate how aging and exposure to ongoing trauma in the region might have affected the course of PTSD. In children and adolescents, PTSD symptoms may present differently depending on developmental stage and severity of traumatic exposure (American Academy of Child and Adolescent Psychiatry 1998).

General medical conditions may occur as a direct consequence of the trauma (e.g., head injury and burns). In addition, chronic PTSD may be associated with increased rates of adverse physical outcomes, including musculoskeletal problems and cardiovascular morbidity (Beckham et al. 1997, 1998, Schnurr and Green 2003).

**Differential Diagnosis**

PTSD symptoms may overlap with symptoms of a number of other disorders in the DSM-IV-TR. Both PTSD and adjustment disorder are etiologically related to stress exposure.
PTSD may be distinguished from adjustment disorder by assessing whether the traumatic stress meets the severity criteria described earlier. Also, if there are an insufficient number of symptoms to qualify for the diagnosis, this might merit a diagnosis of adjustment disorder.

Specific phobias may arise after traumatic exposure. For example, after an automobile accident, victims may develop phobic avoidance of traveling, but without the intrusive or hyperarousal symptoms. In such cases, a diagnosis of specific phobia should be given instead of a diagnosis of PTSD.

The criteria set for generalized anxiety disorder include a list of six symptoms of hyperarousal, of which four are common to PTSD: being on edge, poor concentration, irritability, and sleep disturbance. PTSD requires both reexperiencing symptoms and avoidance symptoms, and the worry in PTSD is focused on concerns about reexperiencing the trauma. In contrast, the worry in generalized anxiety disorder is about a number of different situations and concerns. However, it is possible for the two conditions to co-occur.

In obsessive–compulsive disorder (OCD), recurring and intrusive thoughts occur, but the patient recognizes these to be inappropriate and unrelated to any particular life experience. OCD is a common comorbid condition in PTSD and may develop with generalization (e.g., compulsive washing for months after a rape to reduce contamination feelings). It may also develop by activation of an underlying OCD diathesis. If the content of the ruminative thinking is focused solely on the traumatic event, this may indicate intrusive reexperiencing symptoms and be better accounted for by PTSD than OCD.

Autonomic hyperarousal is a cardinal part of panic attack, which may indicate a diagnosis of panic disorder. To distinguish between panic disorder and PTSD, the therapist needs to assess whether panic attacks are related to the trauma or reminders of the same (in which case they would be subsumed under a diagnosis of PTSD) or whether they occur unexpectedly and spontaneously (in which case a diagnosis of panic disorder would be justified).

Depression and PTSD share a significant overlap, including four of the criterion C cluster symptoms and three of the criterion D cluster symptoms. Thus, an individual who presents with reduced interest, estrangement, numbing, impaired concentration, insomnia, irritability, and sense of a foreshortened future may manifest either disorder. PTSD may give rise to depression as well, and it is possible for the two conditions to coexist. In a few instances, a patient with prior depression may be more vulnerable to developing PTSD. Reexperiencing symptoms are present only in PTSD.

Dissociative disorders also overlap with PTSD. In the early aftermath of serious trauma, the clinical picture may be predominantly one of the dissociative states (see the section on ASD). ASD differs from PTSD in that the symptom pattern occurs within the first few days after exposure to the trauma, lasts no longer than 4 weeks, and is typically accompanied by prominent dissociative symptoms.

More rarely, PTSD must be distinguished from other disorders producing perceptual alterations, such as schizophrenia and other psychotic disorders, delirium, substance use disorders, and general medical conditions producing psychosis (e.g., brain tumors).

Differences in Developmental, Gender, and Cultural Presentations

There are some age-specific developmental differences in how children and adolescents present with PTSD compared to adults with PTSD. For instance, there are documented differences in arousal modulation, cause-and-effect reasoning, language and conceptual skills, and social information processing; these skills may cause different manifestation of PTSD symptoms in children and adolescents, particularly in how children process and understand the traumatic stressor (Vernberg and Johnston 2001). There are also differences in symptom presentation between children and adults, as noted in DSM-IV-TR criteria. Gender differences have been extensively studied in adult trauma populations, with the preponderance of evidence suggesting that men are more likely to be exposed to trauma but women are significantly more likely to develop PTSD from trauma exposure and to have a longer persistence of symptoms (Breslau 2001). Some researchers argue that this increased risk of PTSD in women is due to the types of traumatic experiences experienced by women, including sexual victimization histories (Cortina and Kubik 2006). There may also be differences in the set of symptoms endorsed by gender, with a recent study finding that women were more likely to endorse reexperiencing and arousal symptoms, while men were more likely to report detachment and numbing (Peters et al. 2006), a finding that is consistent with prior research. Finally, it appears that PTSD is represented similarly across diverse ethnic and cultural backgrounds; however, the disclosure of trauma, level of social support, and interpretations of suffering and traumatic exposure may significantly vary across cultures and should be considered in the context of assessment and treatment for PTSD (Keane et al. 2006).

Etiology and Pathophysiology

The Event

PTSD is defined in terms of etiology as much as phenomenology. The disorder cannot exist unless the individual has been exposed to a traumatic event with a particular set of properties. Community-based epidemiological studies suggest that up to 70% of individuals will experience at least one traumatic event meeting criterion A(1) over the course of their lifetime (Breslau et al. 1991, Kessler et al. 1995, Norris 1992). The relative severity of the traumatic event, predisposing factors, and peritraumatic environmental factors must all be considered in understanding the etiology of PTSD. In most instances, occurrence of the disorder represents the outcome of an interaction among these three groups of factors.

The likelihood of developing PTSD with regard to the nature of the event was reviewed by March (1990, 1993). A consistent relationship occurred between magnitude of stress exposure and risk of developing PTSD. This association held up in many different trauma populations in adults and children. A more recent meta-analysis across 49 studies (Brewin et al. 2000) found an average weighted effect size of $r = 0.23$ between severity of trauma exposure and PTSD severity, suggesting a modest but statistically significant relationship between these two variables of interest. A dose–response model of PTSD has largely been adopted, in which symptom severity is a function of trauma severity (Keane et al. 2006).
To provide further context for this relationship, here are some examples of these findings across some representative studies. In the St. Louis ECA study, PTSD rates were three times higher in wounded Vietnam veterans than in nonwounded veterans (Helzer et al. 1987). In the North Carolina ECA study, PTSD was much more likely to occur in sexual assault victims who were physically injured than in those who were noninjured (Winfield et al. 1990). Other studies have shown similar results in Vietnam veterans (Kulka et al. 1990) and victims of a volcanic eruption (Shore et al. 1986).

In children, Pynoos et al. (1987, 1993) showed that physical proximity to the stressful event was linearly related to the risk of PTSD symptoms in two different populations.

March (1993) concluded that besides the objective event characteristics—namely, actual or threatened death or injury or threat to physical integrity—cognitive and affective responses to the stressor are also important in determining the likelihood that PTSD will develop. In particular, the experience of intense fear, helplessness, or horror is a determinant of a person’s likelihood to develop PTSD.

The range of defined events that may be considered traumatic has increased over the years, which is likely due to a change in definition from the DSM-III-R to the DSM-IV-TR. In DSM-III-R, a traumatic event was considered to be an event “outside the range of human experience.” This definition was modified in DSM-IV-TR to indicate that a traumatic event is defined as an event that involves experiencing or witnessing actual or threatened death or serious injury or learning about an unexpected or violent death and having a response that involves intense fear, helplessness, or horror. There are medical/surgical events (Shalev 1990), such as a cancer diagnosis or open-heart surgery that have been documented to meet criterion A (DSM-IV-TR criteria for PTSD) in some cases; however, inclusion of such traumatic stressors is somewhat controversial and the range of inclusion varies across studies.

Genetic Factors

The field of genetics has begun to explore complex mental health diagnoses and what genes are necessary and sufficient for the development of these disorders (Koenen 2003, Roberts et al. 2006). Although there is limited research conducted thus far on the genetics of PTSD, it is presumed that many different genes may contribute to inherited liability for PTSD. Several reviews have been conducted to examine genetic factors, such as familial psychopathology to the development of PTSD. For instance, Connor and Davidson (1997) reviewed many of the complexities involved in studying familial risk factors of PTSD. From the available literature, which is based on male combat veterans, general population surveys and rape-trauma-related PTSD, there is evidence to suggest that anxiety and depression in families is a risk factor for PTSD (Davidson et al. 1998). Another meta-analytic review of risk factors suggested an effect size of 0.17 for family of origin psychopathology (Ozer et al. 2003). This is a small but significant effect size which suggests that those who reported a family history had higher rates of PTSD than those without such a family history.

Genetic heritability of PTSD can also be considered through examination of twin studies. For instance, a twin study of Vietnam veterans concordant and discordant for combat exposure has shown that a significant part of the variance is explained on the basis of genetic factors with respect to all three (symptom clusters: intrusive, avoidant, and hyperarousal symptoms) (True et al. 1993). McLeod et al. (2001) examined the role of genetic and environmental influences on the relationship between combat exposure, PTSD symptoms, and alcohol use in 4072 male–male twin pairs; the authors tested three hypotheses: (1) alcohol use and PTSD may share an environmental risk factor (i.e., combat) that increases the possibility that they will occur together; (2) the relationship between PTSD and alcohol problems is that one may develop as a consequence of the other; and (3) PTSD and alcohol problems occur together because of a shared vulnerability that increases risk for both disorders. Their analyses supported hypothesis (3); the same additive genetic influences that affect the environmental influences of combat exposure also include the level of alcohol use and level of PTSD symptoms. It is important to note, however, that specific unique environmental factors the twins did not share were more important than were genetic factors for combat exposure and PTSD symptoms, whereas environmental influences appeared about equally important as genetic influences on alcohol use. These results were consistent with previous findings by this group (McLeod et al. 2001).

Overall, the evidence suggests that psychiatric history, both personal or in family members, increases the likelihood of being exposed to a trauma and developing PTSD once exposed (Hidalgo and Davidson, True and Lyons 1999).

King et al. (2001) have developed a congenital learned helplessness animal model, in which rats genetically bred for learned helplessness behavior, exhibited physiologic symptoms of analgesia, learning deficits, and hyporesponsivity of the hypothalamic–pituitary–adrenal (HPA) axis similar to those observed in humans with PTSD. HPA axis hypoactivity, physiologic markers of increased arousal, and increased acoustic startle response are all potential PTSD-associated traits that might be susceptible to genetic analysis. However, the capacity of these traits to distinguish PTSD from non-PTSD patients and their familial pattern must be better defined before they can be employed in genetic studies.

Neurobiological Factors

Identification of biological changes related to PTSD has provided hypotheses for understanding how some individuals develop PTSD in response to a traumatic event, whereas others do not (Yehuda 2002). As summarized by Yehuda (2002), patients with chronic PTSD have increased circulating levels of norepinephrine (Yehuda et al. 1998) and increased reactivity of the alpha-2-adrenergic receptors (Southwick et al. 1993). These changes have been hypothesized to possibly account for some of the somatic symptoms that occur in individuals with PTSD. Neuroanatomical studies have implicated alterations in the amygdala and hippocampus in patients with PTSD (Rauch et al. 2000). Functional magnetic resonance imaging and positron-emission tomography have demonstrated increased reactivity of the amygdala and anterior paralimbic region to trauma-related stimuli (Lieberzon et al. 1999). Furthermore, in response to trauma-related stimuli, there is decreased reactivity of the anterior cingulate and orbitofrontal areas (Shin et al. 1999). These biological alterations suggest that there may be a neuroanatomical substrate for symptoms (intrusive recollections and
other cognitive problems) that characterize PTSD (Schnuff et al. 2001, Vasterling et al. 1998). However, it is unknown whether these changes are preexisting, a result of traumatic exposure, or a result of having PTSD (Pitman 2001).

**Symptomatic Nervous System Alterations**

A meta-analytic review found a positive association between the diagnosis of PTSD and basal cardiovascular activity (Buckley et al. 2001). Particularly, individuals with a current PTSD diagnosis had a higher resting HR relative to both trauma-exposed individuals without a PTSD diagnosis and nontrauma-exposed controls. An additional analysis revealed that differences were greatest in studies with the most chronic PTSD samples (Buckley and Kaloupek 2001). A more recent investigation of basal cardiovascular activity (Buckley et al. 2004) and ambulatory activity (Beckham et al. 2002, 2006) found similar results. In addition, there are two recent studies suggesting that parasympathetic activity (i.e., baroreceptor sensitivity) may also be impaired among those with PTSD (Hughes et al. 2006, in press). Along with increased 24-hour urinary catecholamines, results suggest dysregulation in sympathetic tone and parasympathetic tone (Pitman 1993). There has been repeated demonstration that there is heightened sympathetic arousal in PTSD patients when reexposed to the original trauma in controlled settings (Buckley et al. 2001).

Although a conditioning model provides a viable explanation of the process through which trauma-related cues may generate the heightened physiological responses characteristic of PTSD, it does not explain why some individuals develop PTSD when exposed to traumatic events, while others do not. It has been hypothesized that differential susceptibility to developing PTSD might be attributable in part to individual differences in conditionability, such that some individuals more readily acquire and maintain a conditioned response compared with others, and thus may be more likely to develop PTSD after a traumatic event (Keane et al. 2006). A single study has provided support for this hypothesis, finding greater conditionability in individuals with PTSD (Orr et al. 2000). However, further study is needed to evaluate whether this conditionability is a precursor or consequence of PTSD.

There is evidence of brain dysfunction in individuals with PTSD, as evidenced by abnormalities in evoked potentials. For example, as reported by Pitman et al. (1999), electroencephalographic event-related potential (ERP) response abnormalities in PTSD include reduced P2 amplitude at high stimulus intensities, impaired P1 habituation, and attenuated P3 amplitude to target auditory stimuli. Larger P3 and N1 amplitude responses and shorter P3 and N1 latencies have been reported in PTSD subjects in response to trauma-related stimuli. Based on a review of these studies (Pitman et al. 1999), these ERP findings suggest that PTSD patients have increased cortical inhibition to high-intensity stimuli, impairments in memory and concentration, auditory gating deficits, and heightened selective attention to trauma-related stimuli. These findings are fairly consistent across studies, with a recent meta-analysis suggesting similar changes in information processing following development of PTSD (Karl et al. 2006).

Further, there is some evidence that psychophysiological response to acute trauma exposure may predict the development of PTSD. Shalev et al. (1998) demonstrated that on arrival to the emergency department, regardless of whether PTSD ultimately developed, survivors of traumatic events showed elevated HRs, which were normal at later assessment occasions. However, those who subsequently developed PTSD showed higher emergency department and 1-week HRs than those who did not.

**Neuroendocrine Factors**

The HPA axis has been the most extensively studied neuroendocrine system in PTSD (Southwick et al. 2005, Yehuda 2002, Yehuda et al. 1991). These studies have summarized the principal findings in the literature as follows: reduced 24-hour urinary cortisol excretion, supersuppression of cortisol after low-dose dexamethasone administration, blunting of corticotropin in response to corticotropin-releasing hormone, and increased numbers of glucocorticoid receptors. Their interpretation of these findings suggest that chronic PTSD is accompanied by supersuppression of the emergency HPA response to acute stress. The authors speculate that this may result from the organism’s attempt to protect itself from the potentially toxic effect of high levels of corticosteroids that might occur with repeated exposure to stress or from reminders of the trauma. In further support of the importance of HPA axis alteration in PTSD is the finding (Yehuda et al. 1991) that glucocorticoid receptor changes also correlate with the severity of PTSD symptoms, but not with the less specific anxiety and depressive symptoms measured on other rating scales. In a large sample of Vietnam veterans, combat-exposed veterans with current PTSD had lower cortisol compared to noncombat-exposed veterans without PTSD or combat-exposed veterans with lifetime PTSD but without current PTSD (Boscarino 1996). Lower levels of circulating cortisol and blunted HPA axis response have been demonstrated in both human and other animal models (e.g., Cohen et al. 2006, Santa Ana et al. 2006).

Further evidence for abnormalities in neurotransmitter regulation comes from provocation studies conducted with Vietnam veterans. Administration of yohimbine, an alpha-2-adrenergic antagonist, provoked symptoms of PTSD in combat veterans who had PTSD, as did the serotoninergic challenge with m-chlorophenylpiperazine. Of considerable interest is that there was no overlap between these two groups, suggesting some selectivity in the way in which neurotransmitter systems can be affected between individuals (Krystal et al. 1989, Southwick et al. 1993). Finally, evidence to support alteration of noradrenergic and serotoninergic pathways in PTSD comes from the clinical effects of medications that are selective for these neurotransmitter systems, as discussed later. The opioid system has also been investigated, but less extensively and without any consensus being obtained. One early study (Pitman et al. 1990) found the existence of a naloxone-reversible analgesia in combat veterans exposed to the reminders of the trauma.

**Sleep Studies**

Studies support that there are two distinct, but possibly interrelated, types of sleep complaints in individuals with PTSD: nightmares that replicate traumatic events and impairment in initiating and maintaining sleep (Harvey et al. 2003, Neylan et al. 1998). Data further suggest that sleep problems in PTSD can also include excessive motor activity
and awakenings with somatic anxiety symptoms (Inman et al. 1990, Mellman et al. 1995). There is support for these complaints using polysomnography studies, particularly in reduced sleep time or efficiency and increased awakenings in the PTSD patients (Mellman in press). There has also been documentation of PTSD subgroups with breathing-related sleep disorders. Although most studies have involved combat veterans, more recent studies have included civilian PTSD populations (Krakow et al. 2001). Initial data indicate that for up to 2 months following exposure to trauma, development of PTSD is associated with a more fragmented rapid-eye-movement sleep (Harvey et al. 2003, Mellman et al. 2001). Occasionally, a discrepancy is noted between subjective accounts of sleep and objective findings, with individuals with PTSD perceiving poorer sleep than what is reflected in sleep studies (Harvey et al. 2003). However, sleep disruption, whether based on subjective or objective measures, is a biological factor that contributes to distress and increases functional impairment in trauma-exposed individuals.

Psychological Factors

Behavioral Models

Conditioning theory has been helpful in explaining the process through which stimuli that are associated with a traumatic event can alone elicit intense emotional responses in individuals who have PTSD (Guthrie and Bryant 2006). Cues (i.e., conditioned stimuli) that are present at the time of the trauma (the unconditioned stimulus) become associated with the unconditioned emotional response (fear, helplessness, or horror). Following the traumatic event, these cues alone can then repeatedly elicit the strong emotional response. For example, a woman who has been raped (unconditioned stimulus) in a dark alley (conditioned stimulus) by a man (conditioned stimulus) and has an intense fear response (unconditioned response) may demonstrate a fear response (now the conditioned response) when she sees a dark alley (conditioned stimulus) or is in the presence of a man (conditioned stimulus). Avoidance behaviors develop to decrease anxiety associated with the conditioned stimuli. For example, the woman who has been raped may avoid going outside when it is dark and also avoid being in the company of men. Behavioral treatments using exposure principles require confrontation with the feared situation and may ultimately lead to reduction of anxiety (Nemeroff et al. 2006).

Cognitive Models

Exposure to a severe or unexpected event may result in an inability to process and assimilate the experience adequately or to deal effectively with its impact (Resick and Schnicke 1992, 1996). A period of prolonged, difficult, and often incomplete assimilation occurs. The experience is kept alive in active memory, intruding itself into awareness either during the day or at night. The pain of the unbidden experience is followed by active attempts to avoid reminders of the trauma. These intrusive and avoidance phases often alternate. In general, the assumption of these cognitive theories is that exposure to trauma disrupts previously held beliefs about the world and that maladaptive belief changes may contribute to distress and functional impairment among trauma survivors (Boesch et al. 2001).

Foa and Kozak (1986) proposed that fear can be considered a cognitive structure with three elements: stimulus, response, and meaning. To reduce fear, the fear memory must first be activated and then new information provided to modify the fear structure. Cognitive interventions can be used to recognize and change maladaptive cognitions and to replace interpretations of danger by realistic or safer interpretations, with the ultimate hope that the patient will integrate the new information into the fear structure, leading to a more realistic appraisal of the degree of danger.

Social/Environmental Factors

Although systematic research is scant, it may be that individuals exposed to repeated or continuous trauma, particularly of an interpersonal nature, may be more likely to develop PTSD. Trauma involving loss of community or support structures is likely to be particularly damaging. Because social support has been held to produce a buffering effect, lack of support might be considered an additional vulnerability factor. Women are at more risk than men for PTSD.

Treatment

Treatment Goals

General principles of treating PTSD involve explanation and destigmatization, which can be provided to both the patient and the family members. This often includes psychoeducation about basic PTSD symptoms and the way in which it can affect behaviors and relationships. Information can be given about general treatment principles, pointing out that sometimes cure is attainable but that at other times symptom containment is a more realistic treatment goal, particularly in chronic and severe PTSD. Regaining self-esteem and attaining greater control over impulses and affect are also desired in many instances. Information can be provided as to appropriate literature, local support groups and resources, and names and addresses of national advocacy organizations. If the therapist attends to these important issues early in treatment, the patient is able to more readily build trust and also to appreciate that the therapist shows a good understanding of both the condition and the patient.

PTSD is sometimes comparatively straightforward to treat and at other times, it is more complicated. Treatment by a mental health provider is often warranted to address the problematic symptoms of PTSD. There has also been recent interest in integrating PTSD assessment and intervention in primary care settings, as traumatized individuals are often more comfortable seeking assistance from their primary care provider. Therefore, primary care may be a useful avenue to reach a larger population of trauma survivors who may need mental health assistance. Once the individual is identified and a provider is involved, the initial history taking can evoke strong affect to a greater degree than is customarily found in other disorders. In fact, it may take several interviews for the details to emerge. A sensitive yet persistent approach is needed on the part of the interviewer. During treatment, although the mental health care provider will clearly want to impart a sense of optimism to the patient, it is also a reflection of reality to point out early that recovery may be a slow process and that some symptoms (e.g., phobic avoidance and startle response) may persist. It is important for the mental health care provider to be comfortable in hearing
and tolerating unpleasant affect and sometimes horrifying stories from trauma survivors, resulting in a nonverbal and accepting demeanor. In addition, providers need to pay attention to secondary traumatization issues; this refers to the impact on mental health professionals being repeatedly exposed to the disturbing details of traumas and the often dramatic emotional impact felt by the trauma survivor. It is important for providers to carefully monitor their emotional responses to this exposure and how this may affect the therapeutic relationship (Adams et al. 2006).

There are times when decompensation occurs to such an extent that the provider will have to judge whether hospitalization is indicated. Denial of particularly painful issues can lead to avoidance of therapy and missed appointments. Similarly, the emergence of unpleasant or troubling side effects with medication may also lead to treatment discontinuation. At all times, it is advisable for the therapist to remind the patient that difficult issues will arise periodically and that, rather than the patient taking unilateral action to drop out of treatment, these issues are best discussed with the therapist, with the hope that they can be resolved and further treatment progress can be made.

At times, it is helpful to engage the spouse or significant family member in treatment because of the difficulties and stresses to which they may be subjected. Furthermore, they can provide information that might help the therapist to acquire a better grasp of the severity of symptoms as well as their effects on the lives of others. For example, sleeping partners can give a more graphic account of the nocturnal disturbances that may occur in symptomatic patients with PTSD. They may also provide important supplementary information as to the effects of poor impulse regulation or impaired memory or concentration on daytime behaviors in an individual.

Given that many patients with PTSD are receiving more than one treatment, coordination of effort between providers is important. At times, different philosophical persuasions may result in one provider being somewhat less supportive of another’s efforts, a situation in which everybody loses. Mutual respect for each other’s efforts is essential if optimal progress is to be made by the patient.

Specific treatment approaches include the use of pharmacotherapy, psychotherapy, anxiety management, and attention to the general issues described earlier.

Pharmacotherapy

PTSD may be accompanied by enduring neurochemical and psychophysiological changes and can lead to substantial impairment and distress. Sometimes the intensity of symptoms is severe enough to preclude the effective use of trauma-focused psychotherapy. In these situations, among others, the use of medication should not be delayed unnecessarily. Initial studies showed benefit for the tricyclic antidepressant and monoamine oxidase inhibitor medications. However, the selective serotonin reuptake inhibitors (SSRIs) and serotonin–norepinephrine reuptake inhibitors (SNRIs) have now replaced these as first-line agents (Davidson 2006). SSRIs have demonstrated superiority over placebo in multiple well-controlled, double-blind trials in the past decade, and sertraline and paroxetine are two SSRIs officially indicated for the treatment of PTSD in the United States and elsewhere (Davidson 2006). Two large trials have more recently demonstrated superior efficacy of the SNRI drug, venlafaxine-extended release, relative to placebo in PTSD (Davidson et al. 2006a, 2006b). Although serotonin reuptake inhibitors are the pharmacotherapy of first choice for PTSD, other medications have also demonstrated some efficacy in managing symptoms in trauma populations, but only in small samples, or in uncontrolled trials. The main groups of medications relevant to the treatment of PTSD along with dose ranges and dose increment recommendations can be found in Table 72–1. These recommendations are from the International Psychopharmacology Algorithm project and adapted from a previously published paper (Connor and Butterfield 2003). Please note that these specific medications were included due to the empirical support found for their use within the PTSD literature and the dosages are different than what might be recommended for other mental health conditions. A suggested sequencing of treatment is outlined in Figure 72–2.

Two double-blind clinical trials in a combined total of more than 100 patients support the efficacy of amitriptyline and imipramine in combat veterans with PTSD (Davidson et al. 1990, Frank et al. 1988). In both studies, the medication was effective on intrusive PTSD symptoms, and, to a weaker extent, on avoidant symptoms. Of importance was that clinical efficacy occurred in patients who did not suffer from depressive illness, suggesting that the effect of tricyclic agents in PTSD is independent of antidepressant properties. In fact, Davidson et al. (1993) found that response was inversely correlated with baseline depression level.

Phenelzine has been found to be effective in symptom reduction based on Kosten et al. (1991). Of note was the finding that avoidant symptoms improved to a much greater degree with phenelzine than with the tricyclic agents. However, the side effects of phenelzine limit its use to a third- or fourth-line drug to be used only when other, safer medications have failed to work. Several placebo-controlled trials have shown positive effects for the SSRI medications, specifically fluoxetine (Connor et al. 1999, Martenyi et al. 2002, 2003, van der Kolk et al. 1994), sertraline (Brady et al. 2000, Davidson et al. 2001), and paroxetine (Marshall et al. 1998, Tucker et al. 2001). Two trials have shown benefit for venlafaxine-extended release, one of which was a 6-month trial, demonstrating sustained efficacy, with high rates of remission at study end point (Davidson et al. 2006a, b). One novel and important finding from the 6-month study was the ability of medication to increase personal resiliency to a greater degree than placebo, the first time this has been demonstrated, to our knowledge. It is possible that optimal response to an SSRI takes over 6 months (Londborg et al. 2001). Data support positive effects for SSRI in men and women and in adults who have survived all major classes of trauma (e.g., combat, sexual violence, nonsexual violence, and accident). Each of these medications has broad-spectrum properties across the full symptom range of the disorder, as well as improving function and, perhaps, resilience, or stress coping (Connor et al. 1999, Davidson 2006). They also support the benefit of SSRI drugs in those with and without comorbid major depression (Brady et al. 2000, Connor et al. 1999, Davidson et al. 2001, in press, Marshall et al. 1998, van der Kolk et al. 1994).

Because PTSD is a chronic disorder, there is a significant risk of relapse, especially if treatment is discontinued prematurely. Bearing this out are three studies that report higher rates of relapse when an SSRI is replaced by a placebo,
as compared to groups who remained on their drug, over a period of 1 year or more (Davidson et al. 2001a, 2005, Martenyi et al. 2003).

There have been a number of open studies, suggesting benefit of carbamazepine, propranolol, clonidine, and valproic acid. There have also been two negative double-blind placebo-controlled trials of desipramine and phenelzine (Davidson 1992); however, treatment length in these two studies may have been too short because in the study by Davidson et al. (1990) it was not until week 8 that amitriptyline became superior to placebo.

At this point, the indications for antipsychotic and mood-stabilizing drugs are poorly defined, but clinical experience suggests that they continue to have a role in the pharmacologic treatment of PTSD. It is encouraging to know that five double-blind, placebo-controlled, augmentation studies of either olanzapine or risperidone have shown positive benefits for the drug, in combat veterans and noncombat veterans, with PTSD. Almost all patients were already taking an SSRI, to which they had shown partial response (Bartzokis et al. 2005, Hamner et al. 2004, Monnelly and Ciraulo 1999, Reich et al. 2004, Stein et al. 2003). Antipsychotic medications appear to be useful in enhancing sleep, reducing aggression, and otherwise treating different aspects of PTSD. We do not have adequate data to suggest in what ways, if any, anticonvulsants, mood stabilizers, or other drugs are helpful. One exception may be prazosin, the alpha-1-adrenergic antagonist, for which there is some evidence that, in augmentation to an antidepressant, it leads to improvement in nightmares (Raskind et al. 2003). The appropriate role for the use of benzodiazepines is not well defined. The antiphobic and antiarousal effects of the benzodiazepines should, in theory, be helpful in PTSD. However, withdrawal from short-acting benzodiazepines may also introduce an additional set of problems with intense symptom rebound. In patients who have a propensity to abuse alcohol and other substances, benzodiazepines are not recommended.

Overall, the antidepressants and, to a lesser extent, the atypical antipsychotics are the most useful, and best studied, medication groups in treating PTSD. Mood stabilizers, hypnotics, beta-blockers, alpha-2-agonists, alpha-1-antagonists, and anxiolytics have a less clearly defined place. Preliminary research regarding the use of beta-blockers, specifically taking propranolol immediately after trauma exposure, may prevent some symptoms of PTSD and reduce

*See elsewhere for available levels of evidence to support use of each medication. Dose increments to proceed unless clinical response of at least 50% reduction in symptom severity or due to problematic side effects. Issues of drug interactions are clinically important but not addressed in this particular table. Adequacy of treatment trial suggested is 12 weeks at the maximum tolerated dose for all of the above medications.
IPAP Post-Traumatic Stress Disorder (PTSD) Algorithm v. 1.0 (June 2005)

1. Diagnosis of PTSD

2. Consider at diagnosis and each evaluation
   - A. Suicidality
   - B. Comorbid diagnoses
   - C. Insomnia or nightmares
   - D. Psychosis
   - E. Substance Abuse
   - F. Noncompliance
   - G. Ongoing trauma
   - H. Women and Childbearing
   - I. Cultural issues
   - J. Litigation issues
   - K. Psychosocial treatment

3. SSRI or SNRI (or TCA if unavail):
   - 4–6 weeks evaluation with adequate dose and duration and no intolerance
   - All systems unresponsive, either
     - Partial
     - Full

4. Resp?
   - Yes
   - Inadequate response with:
     - Persistence insomnia, nightmares
     - Comorbid psychotic
     - Comorbid depression, anxieties, stable comorbid bipolar

5. Continue at least 1 year
   - Yes
     - Inadeq response to core PTSD Sx
     - 4–6 weeks?
     - Yes
       - Inadequate response to core PTSD Sx
       - Continue at least one year
     - No
       - Adequate
         - Inadequate response with:
           - Core PTSD responses
           - Persistent insomnia, nightmares
           - Psychotic
           - Comorbid depression, anxieties, stable comorbid bipolar

6. Some Sx remain unresponsive?
   - Yes
     - Inadequate response with:
       - Core PTSD responses
       - Persistent insomnia, nightmares
       - Psychotic
       - Comorbid depression, anxieties, stable comorbid bipolar
     - No

7. Augment according to salient symptoms
   - Partial
     - No, general partial response

8. Adjust to maximum tolerated dose

9. Switch w/in SSRI class or betw classes (SNRI, TCA, or α1AA)

10. Response after 4–6 weeks?
    - Yes
      - No
      - Yes
        - Inadequate response with:
          - Core PTSD responses
          - Persistent insomnia, nightmares
          - Psychotic
          - Comorbid depression, anxieties, stable comorbid bipolar

11. Switch to another SSRI or to SNRI or from SNRI to NaSSA

12. Resp?
    - Yes
      - No
      - Yes
        - Add α1AA, low-dose TCA, other sedating antidepressants

13. Add TCA, AAP, anticonvulsant, α1AA, α2A, BDZ, βB, or azipirone; CBT

14. Resp?
    - No
      - Yes
        - Continue at least one year

15. Switch to TCA or MAOI or add third medication from above or re-evaluate Dx; consider PST

16. Add α1AA, low-dose TCA, other sedating antidepressants

17. Resp?
    - No
      - Yes
        - Continue at least one year

18. Switch w/in group or switch to APP

19. Resp?
    - No
      - Yes
        - Continue at least one year

20. Consider obstructive sleep apnea, restless legs syndrome, or other sleep disorders and re-evaluate Dx; consider PST

21. Add AAP (or first-generation AP if unavail)

22. Resp?
    - No
      - Yes
        - Continue at least one year

23. Change AP or add mood stabilizer or anticonvulsant

24. Resp?
    - No
      - Yes
        - Continue at least one year

25. Re-evaluate diagnosis; consider PST

26. Add mood stabilizer, anticonvulsant, Li, or AAP

27. Resp?
    - No
      - Yes
        - Continue at least one year

28. Switch or add from within group

Key: α1AA=α1-adrenergic antagonist; α2A=α2-agonist; AP=antipsychotic; AAP=atypical antipsychotic; βB=beta-blocker; BDZ=benzodiazepeine; CBT=cognitive behavioral therapy; Dx=diagnosis; Li=lithium; MAOI=monamine axidase inhibitor; NaSSA=noradrenergic and selective serotonergic antidepressant; PST=psychosocial treatment; Resp=response; SNRI=serotonin and noradrenaline reuptake inhibitor; SSRI=selective serotonin reuptake inhibitor; Sx=Symptoms; TCA = tricyclic antidepressant.

Figure 72–2 Pharmacotherapy steps for posttraumatic stress disorder. Reprinted with permission from Dr. Kenneth Jobson, International Pharmacotherapy Algorithm Project.

Often, patients need a combination of drugs but polypharmacy should be utilized in a carefully planned fashion. Also, since the time course of response may be slow, it is advisable to persist with a particular course of action for at least 8 weeks before deciding that it has been unhelpful. Partial response can be converted into full remission as long as 6–9 months into treatment. Three relapse-prevention studies have shown the ability of fluoxetine and sertraline to protect against relapse over a 1-year or greater length of treatment.

### Psychosocial Treatments

Despite theoretical differences, most schools of psychotherapy recognize that cognitively oriented approaches to the treatment of anxiety must include an element of exposure (Foa et al. 2000). Because PTSD avoidance of danger that is conditioned by real experience, correction of these “fear structures” requires exposure to ensure habituation. Although a range of possible PTSD interventions has recently been reviewed (Foa et al. 2000), including group therapy, cognitive–behavioral therapy (CBT), eye movement desensitization and reprocessing (EMDR), and psychodynamic therapy, the preponderance of current evidence suggests that the primary effective component of PTSD treatment is prolonged exposure (Rothbaum et al. 2000). Prolonged exposure depends on the fact that anxiety will be extinguished in the absence of real threat, given a sufficient duration of exposure in vivo or in imagination to traumatic stimuli. When using in vivo exposure techniques, patients are asked to confront real-life situations that trigger anxiety (e.g., street where car accident happened or room where assault occurred) and remain in these situations until their anxiety begins to decrease. In imaginal exposure, the patient retells the traumatic experience as if it were happening again, until doing so becomes a pedestrian exercise and anxiety decreases. Between sessions, patients perform exposure homework, including listening to tapes of the flooding sessions and limited exposure in vivo. A review of 12 studies suggests that prolonged exposure is a component of the most well controlled study designs and is associated with positive results (Rothbaum et al. 2000). However, not every patient may be a candidate for exposure. Due to the high anxiety and temporarily increased symptoms associated with prolonged exposure, there are patients who will be reluctant to confront traumatic reminders. Patients in whom guilt or anger are primary emotional responses to the traumatic event (as opposed to anxiety) may not profit from prolonged exposure (Foa et al. 1995, Pitman et al. 1991). More empirical research is needed to evaluate how this efficacious treatment can be most effectively implemented in trauma populations. Additional research is also needed to identify methods to increase patient tolerability of the treatment.

In addition to exposure therapy, the use of EMDR has been empirically supported within PTSD patient populations. According to its creator, EMDR facilitates the accessing and processing of traumatic memories to bring closure and resolution (Shapiro 2001). Patients are asked to identify the most disturbing images of their trauma, including body sensations and a negative cognition about what they learned from the trauma. They are also asked to create a positive cognition that they wish could replace the negative cognition about the trauma. During active treatment, patients are asked to bring to mind the disturbing image, sensations, and the negative cognition while tracking the clinician’s moving finger back and forth in front of their visual field. These tracking sessions continue in order for the patient to focus on whatever changes or new associations have occurred. Tracking is repeated in future sessions until the patient has no further changes; then, more tracking is implemented to reinforce the positive cognition. Although EMDR has been empirically supported in the literature, there is some controversy about the “active ingredient” in EMDR and the restricted access to this treatment protocol through a proprietary company.

Anxiety management techniques are designed to reduce anxiety by providing patients with better skills for controlling worry and fear. Among such techniques are muscle relaxation, self-distraction (thought stopping), control of breathing and diaphragmatic breathing, guided self-dialogue, and stress inoculation training. These techniques focus on enhancing a trauma survivor’s ability to manage negative effect, especially anxiety and anger, and increase their everyday functioning. Although these interventions have less empirical evidence regarding treatment efficacy for PTSD, generally the results are positive and further controlled evaluation across trauma population samples is needed (Rothbaum et al. 2000).

Further, cognitive approaches to the treatment of PTSD have also gained empirical support (Resick and Schnicke 1992, Rothbaum et al. 2000). Overall, cognitive therapy for PTSD focuses on challenging dysfunctional, automatic thoughts that may develop following trauma exposure. (For example, the world is a dangerous place.) This is particularly important because dysfunctional interpretation of the traumatic event may lead to negative mood states, such as anxiety, generalized fear, and self-blame. In a recent comparison of cognitive therapy to imaginal exposure in the treatment of chronic PTSD, both treatments were associated with positive improvements at posttreatment and follow-up, with no differences in outcome between treatments (Tarrier et al. 1999). However, patients who received imaginal exposure were more likely to experience an increase in PTSD symptoms during the treatment course, and those who did were more likely to miss treatment sessions, rate the therapy as less credible, and be rated as less motivated by the therapist.

Other recent approaches have focused on efficaciously treating one aspect of PTSD symptomatology, such as anger (Yehuda 1999) and nightmares (Krakow et al. 2001). Some approaches have focused on specific interpersonal difficulties, such as difficulty dealing with authority figures following combat trauma (Lubin and Johnson 2000). There has also been a recent report of positive results, using interventions to target both PTSD and a comorbid disorder. For example, Triffleman et al. (1999) reported patient improvement using a group intervention to simultaneously treat co-occurring substance abuse and PTSD. Similar support has been found with data from the Seeking Safety Protocol for comorbid PTSD and substance abuse (Najavits 2006). Falsetti et al. (2001) have reported an intervention entitled multiple channel exposure therapy to treat comorbid panic attacks and PTSD.

In contrast to the treatment-efficacy literature for adults with PTSD, the child-focused PTSD literature is primarily...
limited to open trials and case reports (Ruggiero et al. 2001). Ruggiero et al. (2001) underscore that adult treatment approaches need to be empirically evaluated for use in children with PTSD. Although the literature is fairly limited thus far, one recent randomized clinical trial (Cohen et al. 2004, 2005) found trauma-focused CBT to be more effective than conventional child-centered therapy among childhood sexual abuse survivors. The trauma-focused CBT included skills such as expressing feelings; learning basic coping skills; recognizing the relationship between thoughts, feelings, and behaviors; gradual exposure; cognitive processing of the trauma; joint child–parent sessions; psychoeducation about body safety and child sexual abuse; and parent management skills. The child-centered therapy included active listening, reflection, accurate empathy, encouragement to talk about feelings, and limited interpretations when clinically appropriate. Similar research needs to be conducted to determine evidence-based practices for the treatment of child and adolescent PTSD.

As no single treatment for PTSD has been shown to be curative, patient characteristics, characterization of the nature and range of stress responses of trauma victims (McFarlane and Yehuda 2000), partial response (Taylor et al. 2001), treatment combinations, sequencing of treatment approaches, and further well-controlled investigations of current approaches are all important empirical topics to be addressed. For example, in patients unwilling to undergo exposure therapy, teaching of affect management skills may be helpful (Wolfshof and Zlotnick 2001).

Psychodynamic Therapy
Psychodynamically based approaches emphasize the interpretation of the traumatic event as being a critical determinant of symptoms. Treatment is geared to alter attributions, usually by means of slow exposure and through confrontation and awareness of the negative affect that have been generated by the trauma. Conflicted meanings begin to appear, and it is the task of treatment to reinterpret the experience in a more realistic and adaptive fashion. During such treatment, it is important to ensure that the affect intensity is not overwhelming or disorganizing. Obviously, support needs to be provided throughout, and sometimes other treatment approaches are used adjunctively. Excessive and maladaptive behaviors such as avoidance, use of alcohol or working excessively, or risk taking may occur as a means of coping with the experience and need to be identified and addressed.

Using psychodynamic concepts, Horowitz (1973) developed a trauma-focused, time-limited, psychotherapeutic approach. Periods of intrusion are considered an attempt at mastery rather than a failure in defenses, whereas emotional numbness is seen as a result of defensive overcontrol. Overwhelmingly intrusive symptoms are counteracted by means of structuring, and avoidance and numbing are met with procedures to minimize such behavior. With this approach, as with any psychotherapeutic approach, the establishment of a safe therapeutic alliance is essential and medications are used sparingly. The goal of such trauma-focused therapy is to achieve an end point in which the trauma is meaningfully integrated into the survivor’s life schema, with reduction of intensity and frequency of the intrusive and avoidant phases of PTSD. Although this and other psychodynamic approaches await controlled testing, they aspire to reduce all aspects of PTSD symptoms (Kudler et al. 2000).

Roth and Newman (1991) presented a conceptual framework for understanding the emotional impact of sexual trauma. The survivor must come to understand the affective impact of the event so that she or he is no longer preoccupied or driven by negative feelings or self-defeating behaviors. It is also important for the survivor to grapple with the meaning of the trauma so as to reach adaptive resolution. Preliminary studies utilizing this approach show promise of efficacy.

Special Factors Influencing Treatment

Psychiatric Comorbidity
Several important issues of comorbidity need to be considered in the treatment of PTSD. These may suggest either a contraindication to a particular treatment or the need to first treat the comorbid state before embarking energetically on the PTSD problems. Thus, comorbid depression needs to be treated, as it is likely to interfere with the benefits of behavioral therapy or other psychotherapies (Davidson et al. 2004). In fact, as mentioned earlier, in some instances guilt-bound issues may worsen with exposure. A suicidally depressed individual with PTSD needs to be adequately treated before dealing with issues of PTSD, which may in fact worsen suicidality in some instances.

Occasionally, severe depression comorbid with PTSD may need to be treated with electroconvulsive therapy. Although this form of treatment has no proven place as a major intervention for PTSD per se, in comorbid cases it has been noted that PTSD symptoms may also abate when they are tied to the presence of depression. Davidson and Fairbank (1993) reported that amitriptyline is less likely to help combat veterans with PTSD if they have been exposed to more severe forms of combat trauma and also if they have more severe symptoms of depression, anxiety, and PTSD.

General Medical Comorbidity
PTSD patients have been shown to have an increased risk of medical conditions, with particular conditions perhaps being more prevalent (gastrointestinal disease and cardiovascular disease) (Beckham et al. 1998, Boscario 1997, Schnurr and Green 2003, Schnurr and Janowski 1999). There is also evidence that chronic pain and PTSD are commonly associated, even when PTSD has not followed serious physical injury (Beckham et al. 1997). With a focus on the mind–body connection, these medical conditions and bodily symptoms should be addressed concurrently with PTSD treatment.

Demographic Factors
It is not known to what extent sex or age is likely to determine treatment outcome. However, it is generally believed that lack of psychosocial supports can interfere with successful adaptation to trauma and response to treatment (Keane et al. 2006).

Nonresponse to Treatment. A stepwise sequence of approaches may be used in the treatment of PTSD but it must be said that there are no definitive guidelines currently in place. As a result, the particular order in which treatments are considered varies based on individual circumstances.
Also, no uniform definition exists as to what constitutes a good or poor response to treatment. In general, some symptoms of chronic PTSD persist, albeit at a considerably reduced level, in people who have undergone treatment. A summary of the limited information available for predicting response to pharmacotherapy and behavioral therapy in PTSD arising from combat trauma is given elsewhere (Davidson and Fairbank 1993).

**Summary of Treatment**

Whatever the type of treatment administered, a number of goals are common to all and can be summarized as follows: (1) to reduce intrusive symptoms, (2) to reduce avoidance symptoms, (3) to reduce numbing and withdrawal, (4) to dampen hyperarousal, (5) to reduce psychotic symptoms when present, and (6) to improve impulse control when this is a problem.

By reducing troublesome symptoms, a number of other important goals can also be accomplished as well: (1) to develop the capacity to interpret events more realistically with respect to their threat content; (2) to improve interpersonal work and leisure functioning; (3) to promote self-esteem, trust, and feelings of safety; (4) to explore and clarify meanings attributed to the event; (5) to promote access to memories that have been dissociated or repressed when judged to be clinically appropriate; (6) to strengthen social support systems; and (7) to move from identification as a victim to that of a survivor.

The three major treatment approaches, pharmacotherapeutic, cognitive–behavioral, and psychodynamic, all emphasize different aspects of the problem. Pharmacotherapy targets the underlying neurobiological alterations found in PTSD and attempts to control symptoms so that the above treatment goals can be more effectively accomplished. Cognitive–behavioral treatments emphasize confronting traumatic memories through exposure as well as identifying and challenging dysfunctional beliefs about the trauma. The psychodynamic approach emphasizes the associations that arise from the trauma experience and that lead to unconscious and conscious representations. Defense mechanisms that lead to lack of memory, and the contributions from early development, are also brought into play in psychodynamic therapy.

**Issues in the Doctor–Patient Relationship**

Management problems are likely to occur as a result of both therapist-related factors and patient-related factors. With regard to the therapist, it must be recognized that much of the material offered by the patient is charged with affect and, at times, may strain credibility and lead to high levels of doubt. The therapist may fall into the error of being unable to accept such an emotionally charged experience and thus reject or denying its validity. Equally, the therapist may fall into the error of overidentification with the patient such that impartiality is lost. It is important for therapists not to become overinvolved with rescue fantasies or to break down customary therapist–patient boundaries.

Although not unique to PTSD, powerful violent urges may arise in the patient during treatment, which may challenge the therapist’s feeling of safety. Simple strategies, such as considering where the patient and therapist sit with respect to proximity of escape, merit attention. For example, a female therapist dealing with a highly hostile and threatening male patient would do well to be sure that she can exit the room quickly if necessary and not be trapped behind a desk with the patient having control of the exit. Another simple yet important issue calling for attention is whether there is an available alarm if the therapist is dealing regularly with violent or threatening patients.

**ACUTE STRESS DISORDER**

**Diagnosis**

**Definition and Diagnostic Features**

It has long been recognized that clinically significant dissociative states are seen in the immediate aftermath of overwhelming trauma. In addition, many individuals may experience less clinically severe dissociative symptoms or alterations of attention and time sense. Because such syndromes, even when short lasting, can produce major disruption of everyday activities, they may require clinical attention. During triage situations after a disaster, it can be important to recognize this clinical picture, which may require treatment intervention and may also be predictive of later PTSD. As a result of these considerations, a decision was made to include in a new entity, ASD, grouped together with PTSD in the anxiety disorders section. This definition describes stress reactions that occur within the initial month after a trauma has occurred. Essentially, the definition parallels the diagnostic features of PTSD, with identical criterion A requirements for a traumatic stressor(s) and a clinical presentation that includes symptoms of reexperiencing, avoidance, and hyperarousal. One significant difference in diagnostic criteria for ASD is an emphasis on conspicuous dissociative symptoms, of which at least three must be present, as a hallmark feature of ASD. The possible dissociative symptoms in ASD are a subjective sense of numbing, detachment or absence of emotional response, reduced awareness of one’s surroundings, derealization, depersonalization, and dissociative amnesia.

There has been a call for empirical evidence of acutely traumatized individuals to address the inclusion of ASD as a separate diagnostic category from PTSD (Bryant 2003, Bryant and Harvey 1997). The current emphasis placed on acute dissociative responses may be flawed in that there are multiple pathways to PTSD, and trauma survivors who display severe acute stress symptoms without dissociation can develop PTSD (Harvey and Bryant 1999). Other criticisms include the fact that the primary role of ASD is to predict another diagnosis, making it repetitive to have two separate diagnoses; that distinguishing between ASD and PTSD primarily based on duration of symptoms may not be warranted; and that inclusion of ASD in the DSM-IV-TR was made without meeting the same critical review and criteria normally followed for inclusion of other diagnoses. Review of these conceptual issues have recently been published (Bryant 2003).

**Assessment**

Recommendations for assessment of ASD largely follow the general principles addressed above in the PTSD assessment section. It is important to collect clinically relevant information through clinical interview, self-report questionnaires,
collateral informants, and psychophysiological measurement to obtain a thorough assessment of symptom presentation. Two useful assessment tools described in the literature are the Acute Stress Disorder Interview (ASDI; Bryant et al. 1998) and the Acute Stress Disorder Scale (ASDS; Bryant et al. 2000). The ASDI is a structured interview based on DSM-IV-TR diagnostic criteria and appears to have good internal consistency, test–retest reliability, and construct validity. The ASDS is a self-report measure with good reliability and validity data and correlates highly with the symptom clusters on the ASDI. Recently, a self-report scale of ASD has been developed, the ASDS. The scale has demonstrated good test–retest reliability ($r = 0.94$), and in one sample (bushfire survivors), the ASDS predicted 91% of survivors.

**Epidemiology**

Little is known about the epidemiology of ASD as defined in DSM-IV-TR, but some preliminary studies on the prevalence rates of acute PTSD have been published. The following are rates for a representational sample of such studies: 9% among Manhattan residents after the September 11 terrorist attacks (Galea et al. 2002), 13–25% for motor vehicle accident survivors (Harvey and Bryant 1999), 19% for physical assault survivors (Brewin et al. 1999), 24% for survivors of terrorist attack in Israel (Kutz and Dekel 2006), 33% for those who witnessed community violence (Classen et al. 1998), and 94% among a sample of rape victims (Rothbaum et al. 1992). One problem of some postdisaster surveys is that they evaluate subjects at points several months or years after the event. This makes any meaningful assessment of acute stress syndromes difficult. One exception was the self-report-based assessment of morbidity 2 months after an earthquake in Ecuador, which found a 45% rate of acute stress reactions, with the most prominent symptoms being fear, nervousness, tenseness, worry, insomnia, and fatigue (Lim a et al. 1989). Other common acute stress reactions include high rates of numbing, dissociative symptoms, intrusive thoughts, avoidance behaviors, insomnia, concentration problems, irritability, and autonomic arousal (Bryant 2003). It is normative to have at least some levels of distress within the initial month of trauma exposure.

In a study by Koopman et al. (1994) of individuals who had been exposed to a firestorm, the participants showed a high incidence of dissociative symptoms, including time distortions, alterations in cognition and memory, and derealization. Most of these symptoms had lessened by a 4-month follow-up. A study by Bryant and Panasetis (2001) reported that 53% of participants reported panic attacks during their trauma, and those who had symptoms that met criteria for

</tr>
<tr>
<td>G. The disturbance lasts for a minimum of 2 days and a maximum of 4 weeks and occurs within 4 weeks of the traumatic event.</td>
</tr>
<tr>
<td>H. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition is not better accounted for by brief psychotic disorder, and is not merely an exacerbation of a preexisting Axis I or Axis II disorder.</td>
</tr>
</tbody>
</table>

ASD reported more peritraumatic panic symptoms. These data suggest that peritraumatic panic may be related to subsequent PTSD.

Retrospective reports of acute stress symptoms should be interpreted cautiously because of the influence of current symptoms on recall of acute symptoms. In a longitudinal study evaluating report of acute stress symptoms at 1 month and 2 years posttrauma, at least one of the four ASD diagnostic clusters was recalled inaccurately by 75% of patients (Harvey and Bryant 2000).

Course
A recent review of prospective studies of ASD suggests that approximately three quarters of individuals who meet criteria for ASD will later develop full-blown PTSD (Bryant 2003). Therefore, the ASD diagnosis is strongly predictive of the development of PTSD over time. However, it also appears from this review that of those who develop PTSD, only 50% met criteria for ASD within the initial month. This suggests that although ASD may be predictive of later PTSD, there are still a significant group of individuals who develop PTSD without initially meeting criteria for ASD. The emphasis on dissociative symptoms as a requirement for ASD diagnosis may account for this discrepancy (Bryant 2003).

Specific symptoms may affect the course of the disorder and development of subsequent PTSD. For instance, Koopman et al. (1994) indicated that dissociative and cognitive symptoms, which are so common in the immediate wake of trauma, improve spontaneously with time. However, they also found that the likelihood of developing PTSD symptoms at 7-month follow-up was more strongly related to the occurrence of dissociative symptoms than to anxiety symptoms immediately after exposure to the trauma.

Differential Diagnosis
ASD may need to be distinguished from several related disorders (Figure 72–3). Brief psychotic disorder may be a more appropriate diagnosis if the predominant symptoms are psychotic. It is possible that major depressive disorder can develop following trauma and that there may be some overlap with ASD, in which case both disorders are appropriately diagnosed. When ASD-like symptoms are caused by direct physiological perturbation, the symptoms may be more appropriately diagnosed with reference to the etiological agent. Thus, an ASD-like picture that develops secondary to head injury is more appropriately diagnosed as mental disorder due to a general medical condition, whereas a clinical picture related to substance use (e.g., alcohol intoxication) is appropriately diagnosed as substance-induced disorder. Substance-induced symptoms are confined to the period of intoxication or withdrawal. The fact that the symptoms are due to the physiological consequences of head injury needs substantiating by evidence from the history, physical examination, and laboratory testing that the symptoms are a direct physiological consequence of head trauma.

Because ASD by definition cannot last longer than 1 month, if the clinical picture persists, a diagnosis of PTSD is appropriate. Some increased symptoms are expected in the great majority of subjects after exposure to major stress. These remit in most cases and reach the level of clinical diagnosis only if they are prolonged, exceed a tolerable quality, or interfere with everyday function. Resolution may be more difficult if there has been previous psychiatric morbidity, subsequent stress, and lack of social support.

Etiology and Pathophysiology
Little is known about the etiology of ASD specifically, but it is likely that many of the same factors that apply to PTSD are relevant for ASD; that is, trauma intensity, preexisting psychopathology, family and genetic vulnerability, abnormal personality, lack of social supports at the time of the trauma, and physical injury are all likely to increase vulnerability for ASD.

The role of acute arousal in the development of PTSD has been evaluated in one study (Bryant and Harvey 2000). Resting HR and ASD symptoms together were found to account for 36% of the variance in PTSD prediction (Bryant and Harvey 2000). Further, a formula using resting HR following the trauma exposure (HR > 90 beats/minute) and the diagnosis of ASD to predict PTSD development possessed strong sensitivity (88%) and specificity (85%) (Bryant and Harvey 2000).

Treatment
Lundin (1994) reviewed the treatment of acute traumatic stress states and pointed out the six general principles involved in administering any treatment immediately after trauma. These include principles of brevity, immediacy, centrality, expectance, proximity, and simplicity. That is, treatment of acute trauma is generally aimed at being brief, provided immediately after the trauma whenever possible, administered in a centralized and coordinated fashion with the expectation of the person’s return to normal function and as proximately as possible to the scene of the trauma, and not directed at any uncovering or explorative procedures but rather at maintaining a superficial, reintegrating approach.

People most highly at risk, and therefore perhaps most in need of treatment, are as follows: survivors with psychiatric disorders; traumatically bereaved people; children, especially when separated from their parents; individuals who are particularly dependent on psychosocial supports, such as the elderly, handicapped, and mentally retarded individuals; and traumatized survivors and body handlers.

Different components of treatment include providing information, psychological support, crisis intervention, and emotional first aid. Providing information about the trauma is important, as it can enable the survivor to fully recognize and accept all the details of what happened. Information needs to be given in a way that conveys hope and the possibility that psychological pain and threat of loss may be coped with. Unrealistic hope needs to be balanced by the provision of realistic explanations as to what happened. Psychological support helps to strengthen coping mechanisms and promotes adaptive defenses. The survivor benefits if he or she recognizes the need to take responsibility for a successful outcome and is actively involved with this as possible. Crisis intervention is often used after disasters and acts of violence or other serious traumas. Emotional first aid has been described by Caplan (1984) using the six principles presented earlier and is used to achieve any of the following: acceptance of feelings, symptoms, reality, and the need for help; recognition of psychologically distressing issues; identification of available resources; acceptance of responsibility and absence...
of blame; cultivation of an optimistic attitude; and efforts to resume activities of daily life as much as possible.

Civilian trauma survivors with ASD were found to engage in the cognitive strategies of punishment and worry more than survivors without ASD (Warda and Bryant 1998), and CBT has been shown to reduce these strategies and increase the use of reappraisal and social control strategies (Bryant et al. 2001). Social control strategies allow for thought control as a means of managing intrusive thoughts about the trauma in a social context. Reappraisal allows a trauma survivor to functionally manage unwanted thoughts and interpret their trauma in a more adaptive manner. As has been found in treatment outcome research with PTSD, there is evidence that CBT for acute symptoms following trauma exposure has had positive results in reducing the frequency and intensity of problematic symptoms. When examining published randomized clinical trials, four out of five found that individuals receiving CBT experienced greater reduction in acute PTSD symptoms than their comparison groups (Brom et al. 1993, Bryant et al. 1998, 1999, Echeburua et al. 1996, Gidron et al. 2001). In a more recent longitudinal outcome study (Bryant et al. 2006), researchers found that CBT reduced reexperiencing and avoidance symptoms at a 3-year follow-up more so than supportive counseling, suggesting the long-term benefits of early CBT for trauma survivors.

There is sparse investigation as to whether early recognition and effective treatment of acute stress reactions prevent the development of PTSD, although it is safe to assume that they are likely to have beneficial effects in this regard. There was one study reviewed with motor vehicle accident survivors that suggested exposure therapy, and exposure therapy with anxiety management training may be effective in preventing PTSD (Bryant et al. 1999). A more recent technique, critical incident stress debriefing (Mitchell and Everly 2000), has been described as an intervention designed to prevent the development of PTSD but has been found to be ineffective (Carlier 2000, Carlier et al. 2000). Psychological debriefing has been a controversial topic within the trauma literature and has yielded inconsistent efficacy findings. A recent review of randomized clinical trials using debriefing found that there is no conclusive evidence to support using this intervention with acute trauma cases (Litz et al. 2002).

**Clinical Vignette 1**

Ben, a 9-year-old third grader, developed PTSD when a drunken driver struck a car in which Ben was riding. Ben’s mother was severely injured, and Ben broke his left arm and left lower leg. He recalled being extremely frightened as the car careened out of control, coming to rest upside down. However, his worst moments came when he saw the emergency helicopter taking his unconscious mother to the hospital. Ben believed that she was dead or would die and thought that he too might die without her there to help him.

Despite an excellent medical outcome and full recovery for both Ben and his mother, he developed characteristic
Clinical Vignette 2

Mr. R, a 34-year-old married man, was referred for medication management by his counselor. He had been healthy until a life-endangering airplane accident 2 years earlier, in which all passengers were killed except for him. He was still experiencing intrusive memories and reliving of the event when seen, despite having had helpful individual counseling. The events of the accident were engraved in his memory with much clarity, and he could not understand how he survived. He was physically injured, with a broken ankle, severe lacerations of his arm, and damage to his back and face. Whenever he saw a plane, he experienced a resurgence of symptoms, and he was unable to take airplane trips. Whenever he rode in an elevator, the sensations he experienced while ascending or descending reminded him of the incident, and he became upset. He experienced hundreds of nightmares relating to the accident, felt as if he were constantly waiting for something bad to happen, and often found it impossible to direct his attention and his mind away from trauma images and memories. He had become fearful of even going to sleep. There was a general reduction of interest in things, and many of his former hobbies no longer gave him any pleasure. He found doing his job to be extremely difficult and thought about quitting. He revisited the site of the accident on each anniversary.

The initial treatment plan recognized that he had already received helpful individual counseling, the focus of which had been on reliving and retelling the story, accepting the painful consequences, and dealing with feelings of guilt because of his survival. Although he recognized the usefulness of these approaches, the intensity of his symptoms continued to be distressing and troublesome. As a result, it was agreed to initiate treatment with sertraline (25 mg), increasing upward to 50 mg after a week, supplemented by clonazepam (0.25 mg) at night, largely to facilitate sleep and reduce hyperarousal and startle response. It was explained to Mr. R that the sertraline would be expected to help more with the intrusive and avoidant and numbing symptoms. He also completed two self-rating scales for PTSD, the Impact of Events Scale (IES) (Keane et al. 1988) and the Davidson Trauma Scale (DTS) (Davidson et al. 1997). The baseline IES score was 47 (range of scores is 0–88), and the baseline DTS score was 101 (range of scores is 0–136). After 5 weeks, the dose of sertraline was increased to 100 mg/day and the dose of clonazepam remained at 0.25 mg. By the sixth week, his symptom distress was much less, with an IES score of 22 and a DTS score of 49. In other words, there was a greater than 50% reduction of symptoms. On an everyday level, he noticed much less avoidance of going into situations reminding him of the trauma, reduced frequency and severity of nightmares and daytime recollections, and greater ability to focus on important tasks related to his work and family. However, he continued to describe persistent startle response.

Mr. R did not continue his individual therapy, feeling that he had maximal benefit after receiving this form of treatment for more than a year. He continued with his medication for another year and noticed improved ability to deal with situations that might have been extremely distressing to him, including being a direct witness to a fatal traffic accident. He was still unable to take airplane trips. At one point during his medication management, he unilaterally opted to discontinue his medication without discussing it because he experienced sexual difficulties, including a loss of sex drive, which was particularly vexing to him, as he and his wife were attempting to start a family. The use of cyproheptadine proved to be helpful in countering this side effect. He was also involved in litigation after the accident and recognized that it was going to be extremely protracted. The litigation also brought with it a whole new set of problems, in which he felt himself being put in the victim position. He acknowledged that, although much progress had been made and he was much more highly functional, “nothing is quick with this condition” and that he still had a number of symptoms. He was willing to consider the possibility of additional treatment focused on his fear of flying. He also recognized that when he had stopped his medicine, the symptoms came back with a vengeance, and at present he became more compliant in taking his antidepressant and anxiolytic medications.

Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria

The ICD-10 diagnostic criteria for research for PTSD provides a different stressor criterion: a situation or event “of exceptionally threatening or catastrophic nature, which would be likely to cause pervasive distress in almost everyone,” which is similar to the DSM-III-R definition of a traumatic stressor. DSM-IV-TR instead defines a traumatic stressor as “an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others.” Furthermore, the ICD-10 diagnostic algorithm differs from that specified in DSM-IV-TR in that the DSM-IV-TR criterion D (i.e., symptoms of increased arousal) is not required. In contrast to DSM-IV-TR, which requires that the symptoms persist for more than 1 month, the ICD-10 diagnostic criteria for research do not specify a minimum duration.

For ASD, the ICD-10 diagnostic criteria for research differs in several ways from the DSM-IV-TR criteria: (1) primarily anxiety symptoms are included; (2) it is required that the onset of the symptoms be within 1 hour of the stressor; and (3) the symptoms must begin to diminish after not more than 8 hours (for transient stressors) or 48 hours (for...
extended stressors). In contrast to DSM-IV-TR, the ICD-10 diagnostic criteria for research does not require dissociative symptoms or that the event be persistently reexperienced.

References

Diagnosis

Definition and Diagnostic Features
Generalized anxiety disorder (GAD) was first defined in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association (APA) 1980). Introduced as a residual category, GAD was diagnosed only if a patient failed to meet criteria for any other Axis I disorder. The diagnostic criteria were revised substantially in DSM-III-R and DSM-IV-TR to define patients’ worries as “excessive” and “uncontrollable” and to stipulate that worry must be present more days than not for at least 6 months (APA 1987, 1994). The DSM-IV-TR definition of GAD also requires three of six associated symptoms: sleep disturbance, difficulty concentrating, restlessness, irritability, fatigue, and muscle tension. At least some of these symptoms must be present more days than not for 6 months. To warrant a diagnosis of GAD, an individual’s worry and associated symptoms must result in clinically significant impairment or distress. Although no longer a residual diagnosis, GAD is not diagnosed if the patient’s symptoms occur exclusively during a mood disorder, psychotic disorder, posttraumatic stress disorder (PTSD), or pervasive developmental disorder.

Revisions to Diagnostic Criteria
Despite several revisions to the diagnostic criteria, GAD remains among the least reliably diagnosed anxiety or mood disorders (Brown et al. 2001b). This diagnostic unreliability has prompted criticism of the definition of GAD and proposals for revisions to the diagnostic criteria. Although there is consensus that the core feature of GAD is worry or anxious apprehension, debate about the validity and clinical utility of the DSM-IV-TR criteria continues.

Worry Criterion
The GAD worry criterion has elicited numerous criticisms and undergone extensive revisions. In DSM-III-R, the key feature of GAD was defined as excessive and/or unrealistic worry in two or more spheres unrelated to another Axis I disorder. The minimum duration of the symptoms was also lengthened from 1 to 6 months in DSM-III-R, thereby clarifying the boundary between GAD and nonpathological worry or adjustment disorders. Recently, however, Kessler et al. (2006) argued that there is little empirical basis for the current duration criterion. The requirement that worries be “unrealistic” was removed in response to arguments that this criterion was difficult to assess (Abel and Borkovec 1995). The DSM-IV-TR definition of GAD specifies that worries must be “excessive,” pervasive (i.e., occurring more days than not for at least 6 months), and uncontrollable. There is, however, considerable variability in how clinicians determine if a worry is excessive, leading Ruscio et al. (2005) to argue that individuals with nonexcessive worry may warrant a diagnosis of GAD.

Associated Symptoms Criterion
The current associated symptoms criterion represents a substantial shift from previous editions of the DSM. The DSM-III criteria required that four major symptom groups accompany worry: motor tension, autonomic hyperactivity, apprehensive expectation, and vigilance and scanning (APA 1980). In DSM-III-R, a diagnosis of GAD required the presence of at least six of 18 associated symptoms, which formed three clusters (autonomic hyperactivity, motor tension, and vigilance and scanning). In diagnostic interviews, however, patients with GAD endorsed symptoms of autonomic hyperactivity less frequently than symptoms from the other clusters (Brawman-Mintzer et al. 1994). In DSM-IV-TR, only the six most commonly endorsed symptoms from the motor tension and vigilance and scanning clusters were retained (Marten et al. 1993). Despite these empirically driven revisions, both the DSM-III-R and the DSM-IV-TR associated symptoms criteria lack specificity and fail to adequately discriminate patients with GAD from those with depressive disorders (Brown et al. 1995). Indeed, several of the associated symptoms of GAD, including sleep...
Discriminant Validity

Debate over the diagnostic criteria for GAD reflects the conceptual confusion surrounding the disorder. GAD was retained as a formal diagnosis in DSM-IV-TR despite arguments that it did not constitute a separate disorder but consisted of symptoms that could be subsumed under other diagnostic categories (Brown et al. 1994). There is evidence of GAD’s poor discriminant validity, which is perhaps not surprising, given the extensive overlap of GAD’s diagnostic criteria with those of other anxiety and mood disorders. In a study conducted with a large clinical sample, 65% of patients diagnosed with GAD met criteria for an additional mood or anxiety disorder diagnosis (Brown et al. 2001a). This finding lends support to the argument that GAD represents the “basic” anxiety disorder in that its core feature, anxious apprehension, is present in all anxiety disorders (Barlow et al. 1996). GAD features, which overlap significantly with the higher-order trait of negative affect, may also be conceptualized as vulnerability dimensions for other emotional disorders (Brown et al. 1998). In light of the extensive comorbidity among anxiety and mood disorders, some have argued in favor of a “general neurotic syndrome” that assumes a homogeneous diathesis for a heterogeneous expression of symptoms and collapses the spectrum of anxiety and mood disorders into a single entity (Andrews et al. 1996, Andrews et al. 1990). The results of a large-scale study, however, have clarified the distinction between GAD and depression (Brown et al. 1998). In this study of a mixed clinical sample, five DSM-IV-TR constructs (mood disorders, GAD, panic disorder/agoraphobia, obsessive-compulsive disorder (OCD), and social phobia) were defined by questionnaires and clinical interview ratings. The outcome of confirmatory factor analysis supported a five-factor model, rather than a model in which features of GAD and mood disorders were collapsed under a single factor. Correlations among the five factors did suggest areas of overlap. The GAD factor, for example, was most strongly associated with the mood disorder factor, and the OCD factor was most highly correlated with the GAD factor. These patterns of associations are not surprising, given the overlap between GAD and depression and GAD and OCD, as discussed below.

Structural Relationships among Dimensions of Anxiety and Mood Disorders

The aforementioned study examined relationships of dimensional features of DSM-IV-TR disorders and features of the tripartite model of anxiety and depression (Clark and Watson 1991). This model proposes a structure of anxiety and depression consisting of negative affect (or general distress), which is associated with both anxiety and mood disorders; physiological hyperarousal, which is specific to anxiety disorders; and low positive affect (or anhedonia), which is specific to mood disorders. Consistent with theoretical predictions about the nature of anxiety and mood disorders (Clark et al. 1994), the negative affect factor was significantly related to all five disorder constructs (most strongly with GAD and depression), whereas positive affect was significantly inversely related to depression and social phobia only (Brown et al. 1998). In longitudinal analyses, temporal variance in a neuroticism/behavioral inhibition factor fully explained temporal covariance in selected DSM-IV-TR disorder constructs, including GAD (Brown 2007). Consistent with cross-sectional findings, positive affect/behavioral activation predicted significant additional variance in the depression and social phobia latent factors, but not in the GAD factor. Contrary to the predictions of the tripartite model, autonomic arousal in cross-sectional analyses was significantly associated only with the panic disorder/agoraphobia factor (Brown et al. 1998). When negative affect was held constant, the GAD and autonomic arousal factors were inversely related (such that higher levels of worry were associated with lower levels of autonomic arousal). This finding is consistent with laboratory studies of GAD (e.g., Thayer et al. 1996) that indicate an association between worry and autonomic suppression. In summary, negative affect is significantly related to both anxiety and depression, whereas low positive affect is uniquely associated with depression and social phobia. These data suggest a hierarchical relationship between dimensions of temperament and disorder constructs, with neuroticism perhaps serving as a vulnerability factor for several emotional disorders. Despite their phenomenological similarities, GAD and depression may be distinguished by their differential associations with positive affect. Furthermore, GAD is not associated with heightened physiological arousal (after controlling for general distress/negative affect), a finding consistent with the removal of symptoms of physiological arousal from the DSM-IV-TR associated symptoms criterion.

Assessment

Diagnostic Reliability

Several large-scale studies have examined the diagnostic reliability of GAD using semistructured clinical interviews. Based on two independent administrations of the Anxiety Disorders Interview Schedule for DSM-IV: Lifetime Version (ADIS-IV-L), one study indicated that GAD possessed only fair diagnostic reliability (kappa = 0.65) (Brown et al. 2001b). Many cases of inter-rater disagreement involved boundaries between GAD and other disorders, particularly MDD, dysthymic disorder, and anxiety disorder not otherwise specified (NOS). In disagreements involving an anxiety disorder NOS diagnosis, both interviewers agreed that clinically significant symptoms were present, but one did not assign a formal diagnosis of GAD because the number, duration, or severity of symptoms did not meet diagnostic threshold. The most common source of diagnostic disagreement (55%) was difference in patient report, suggesting that the DSM-IV-TR criteria are vague or lack clear, behavioral anchors. Although revisions to the DSM criteria have resulted in improved diagnostic reliability for GAD (Di Nardo et al. 1993), the disorder remains among the least reliably diagnosed anxiety or mood disorders.

Self-Report Measures

Scores on self-report measures may assist clinicians in distinguishing patients with GAD from those with other emotional disorders (see Table 73–1). Individuals with GAD receive significantly higher scores on the Penn State Worry

Questionnaire (PSWQ), a psychometrically valid measure of trait worry (Meyer et al. 1990). The PSWQ also differentiates patients with GAD from those with OCD (Brown et al. 1992, 1993). Other self-report measures designed to assess worry include the Worry Domains Questionnaire (Tallis et al. 1992) and the Worry Scale for Older Adults (Wisocki 1988). The Depression Anxiety Stress Scales (DASS, Lovibond and Lovibond 1995) are useful in the assessment of GAD as well as other emotional disorders. The DASS is a 42-item questionnaire consisting of three distinct subscales. The stress subscale, which assesses general negative affect and tension, is strongly correlated with the PSWQ (Brown et al. 1995). The Generalized Anxiety Disorder Questionnaire-IV (GAD-Q-IV, Newman et al. 2002) is a brief screening measure based on DSM-IV-TR criteria. Although GAD-Q-IV scores evidence moderate concordance with the results of structured interviews (kappa = 0.67), clinicians should not diagnose GAD on the basis of self-report scores alone.

Structured Interviews

The ADIS-IV-L (Di Nardo et al. 1994) is the most widely used interview measure of GAD. Designed to assess both current and lifetime anxiety and mood disorders, the ADIS-IV-L also enables dimensional assessment of GAD symptoms, regardless of whether a formal diagnosis is under consideration. The clinician rates the excessiveness and controllability of several domains of worry and the associated symptoms on a zero to eight scale, with zero indicating the absence of a symptom and eight indicating the most severely interfering and distressing manifestation of the symptom. The assessment of these disorder features along continua allows for the determination of disorder severity and the presence of subthreshold symptoms. Dimensional data may also be more useful than categorical, presence–absence ratings in measuring outcomes of clinical trials (e.g., Brown and Barlow 2005) and as dimensional indicators in studies of latent structure (e.g., Brown et al. 1998). The Structured Clinical Interview for DSM-IV-TR Axis I Disorders also contains a diagnostic section on GAD and has good psychometric properties (SCID-IV, First et al. 1996). The Hamilton Anxiety Rating Scale (HARS; Hamilton 1959) is a 14-item clinician-administered interview designed to assess the severity of anxiety symptoms. Although not designed to assess GAD symptoms in particular, the HARS is frequently used as an outcome measure in treatment trials (e.g., Rickels et al. 2003, Stanley et al. 2003). The HARS contains two subscales that assess psychological and somatic symptoms of anxiety. Unfortunately, the HARS may fail to adequately discriminate between anxiety and depression (Moras et al. 1992). The World Health Organization (WHO) Composite International Diagnostic Interview (WHO-CIDI, Kessler et al. 2004) is a fully structured lay-administered interview that may be used to assign both DSM-IV-TR and International Classification of Diseases (10th ed, ICD-10) diagnoses. The WHO-CIDI, which has demonstrated adequate inter-rater and test–retest reliability, is often used in epidemiological research (Andrews and Peters 1998).

ICD-10 Criteria

Although the diagnostic criteria for GAD found in the WHO’s ICD-10 are similar to the DSM-IV-TR criteria, the differences may be substantial enough to affect prevalence estimates. The ICD-10 definition of GAD, for example, requires at least 6 months of “prominent” tension and worry accompanied by at least four of 22 associated symptoms (see Table 73–2). Notably, the ICD-10 definition does not require that worry be “uncontrollable,” that the symptoms of GAD occur outside the context of a mood disorder, or that they

meet a “clinical significance” criterion. Differences in the two criterion sets resulted in poor inter-rater agreement on large, epidemiological study (Slade and Andrews 2001). Of the 151 people diagnosed with DSM-only GAD, 72 did not meet criteria for the ICD-10 diagnosis because they did not experience one of the four symptoms of autonomic arousal. The remaining 79 individuals did not receive the ICD-10 diagnosis because they also met criteria for panic disorder, phobic anxiety disorder, or OCD. Of the 201 individuals with ICD-only GAD, 144 failed to meet the DSM-IV-TR requirement that worries be excessive and 70 failed to meet the interference/distress criterion. Importantly, individuals with DSM-only diagnoses reported more functional impairment than individuals with ICD-only diagnoses, suggesting that the two criterion sets describe somewhat different syndromes.

**Epidemiology**

Prevalence estimates of GAD vary widely, depending on the diagnostic criteria used and the population examined. The National Comorbidity Survey Replication (NCS-R), which entailed structured interviews of over 9000 individuals in the United States, obtained prevalence estimates of 3.1% and 5.7% for 12-month and lifetime GAD, respectively, using DSM-IV-TR criteria (Kessler et al. 2005a, 2005b). Lifetime prevalence rates were lowest among 18–29-year-olds (4.1%) and individuals 60 years or older (3.65%), with the highest rates found among 45–59-year-olds (7.7%). Of those diagnosed with 12-month GAD, 32.3% experienced a “serious” degree of disability, characterized by a suicide attempt, impairment in multiple roles, bipolar I or II disorder, affective psychosis, violent behavior, or significantly impairing substance dependence. Another large-scale study found a 12-month prevalence rate of 2.07%, with the estimate substantially higher (4.2%) among those also meeting criteria for a 12-month substance abuse disorder (Grant et al. 2004). The lifetime prevalence rate was estimated at 4.1%. Sociodemographic factors associated with increased risk included being female, middle aged, unmarried, and with low income, whereas being black, Asian, or Hispanic decreased risk (Grant et al. 2005).

Prevalence estimates of GAD have been significantly affected by changes in the diagnostic criteria. For example, the lifetime prevalence for DSM-III GAD was estimated as high as 45%, but this figure dropped to 9% under the more stringent DSM-III-R criteria (Breslau and Davis 1985). More recently, researchers have noted that alterations in the DSM-IV-TR criteria for GAD may dramatically affect prevalence rates. Ruscio et al. (2005) found that disregarding the excessiveness criterion resulted in a 40% increase in prevalence estimates. Although GAD with excessive worry was associated with an earlier onset, more chronic course, and greater comorbidity, GAD patients with nonexcessive worry exhibited significant impairment and high rates of treatment seeking. Subthreshold cases of GAD that failed to meet the duration, excessiveness, and associated symptoms criteria were associated with significantly elevated risk for subsequent psychopathology (Ruscio et al. 2007). Although the diagnostic criteria for GAD have been revised substantially, questions remain about their sensitivity and specificity. Revisions to the criteria may not only alter our understanding of GAD’s clinical features, but also dramatically affect the prevalence of the disorder.

**Comorbidity Patterns**

Large-scale studies have indicated that most individuals diagnosed with GAD meet criteria for at least one additional diagnosis. In one study using a large clinical sample, 68% of individuals with a principal diagnosis of GAD met criteria for another Axis I disorder, most frequently MDD, social phobia, or panic disorder with or without agoraphobia (Brown et al. 2001a). Ninety-two percent of individuals with principal GAD met criteria for another lifetime disorder, with 64% meeting criteria for MDD. Notably, adherence to the DSM-IV-TR diagnostic hierarchy rules may lead to significant underestimates of comorbidity. For example, when following these rules, which stipulate that GAD is not diagnosed if its symptoms occur in the context of a mood disorder, only 5% of patients with a principal diagnosis of dysthymic disorder or MDD were also diagnosed with GAD. When the hierarchy rule was ignored, 90% of patients with dysthymia and 67% of patients with MDD also met criteria for GAD. Epidemiological studies have found similar patterns of comorbidity, with GAD most often associated with mood disorders and panic disorder (Wittchen et al. 1994).

GAD is also associated with elevated rates of alcohol and substance use disorders. In one epidemiological study, the prevalence of substance use disorders among individuals with GAD was 19.02%, and the prevalence of an alcohol use disorder was 14.82% (Grant et al. 2005). In another study, 18% of individuals with current principal GAD met criteria for a lifetime alcohol or drug use disorder (Brown et al. 2001a).

Several studies have indicated that GAD is frequently comorbid with irritable bowel syndrome (IBS), a disorder characterized by abdominal pain and abnormal bowel habits (constipation and/or diarrhea) (Blanchard et al. 1990, Sykes et al. 2003). No structural, physiological, or biochemical abnormalities have been found to account for the symptoms, and many studies have indicated that patients with IBS are more likely than healthy controls to have psychiatric illnesses, particularly anxiety and depression (Blanchard et al. 1990). In one study of treatment-seeking IBS patients, 60% also met criteria for GAD (Sykes et al. 2003). The high rates of comorbidity associated with GAD have important implications for treatment. Higher rates of comorbidity are associated with lower rates of remission and greater likelihood of relapse over 12-year follow-up (Bruce et al. 2005). Nevertheless, Borkovec et al. (1995) demonstrated that treatment of GAD may produce significant improvement in comorbid conditions.

**Course**

Many patients with GAD have difficulty pinpointing a clear age of onset or report that their symptoms began in childhood, suggesting a chronic course similar to that observed in personality disorders (Barlow et al. 1986, Sanderson and Wetzler 1991). Several studies, however, have indicated that GAD often begins in adulthood. In one large study with a clinical sample, the mean age of onset was 20.57 years (Brown et al. 2001a). There is some evidence for a bimodal distribution of age of onset in GAD, with earlier-onset GAD associated with higher levels of neuroticism and greater severity and comorbidity (Campbell et al. 2003).

In this study, cases of GAD that were not associated with a precipitating stressor were more likely to be of earlier onset, whereas symptoms emerging in adulthood typically
began in the context of mild-to-moderate stress. A longitudinal study of patients with GAD indicated that many patients (46% of women and 56% of men) experienced episodes of full remission, with symptom-free periods lasting longer in women (Yonkers et al. 2003). The perception of GAD as a chronic, unremitting illness may not, therefore, be entirely accurate. Rather, chronic cases may represent a subgroup characterized by greater comorbidity. Notably, in 66% cases of comorbid GAD and MDD, the symptoms of GAD predated the onset of depression, which lends some support to the argument that GAD represents a prodrome of MDD (Brown et al. 2001a). On average, however, GAD onset is over 7 years prior to the onset of MDD, indicating that patients may experience long periods of clinically interfering worry well before they suffer from an episode of depression.

Differential Diagnosis
Because anxious apprehension is, to some degree, characteristic of all anxiety disorders, assessment of GAD is particularly challenging. Guidelines for differentiating GAD from normal worry and from other emotional disorders are discussed below and in the decision tree presented in Figure 73–1.

Nonpathological Worry
The clinician must determine whether an individual’s worry warrants a diagnosis of GAD or whether it constitutes a normal reaction to a stressor. There is evidence that patients with GAD and nonanxious controls differ in the controllability of their worry rather than its content (Borkovec 1994). In one study, 100% of those diagnosed with GAD using DSM-III-R reported difficulty controlling their worry, compared to only 5.6% of the nonanxious comparison group (Abel and Borkovec 1995). Individuals with GAD are more likely than control participants to report that they worry a large percentage of every day, frequently experience untriggered worry, perceive their worry as difficult to control, and have a larger number of worry spheres. Furthermore, those diagnosed with GAD are more likely than controls to report worry about minor matters (Sanderson and Barlow 1990).

MDD and Dysthymic Disorder
GAD shares several diagnostic features with both MDD and dysthymic disorder, including impaired concentration and sleep disturbance. Because of the substantial overlap between GAD and depression, a DSM-IV-TR hierarchy rule stipulates that GAD is not diagnosed if the symptoms have

---

**Figure 73–1 Diagnostic decision tree.**
occurred within the context of a mood disorder. Therefore, the assessor must determine when the symptoms of GAD onset relative to depression in order to make an accurate diagnosis. Measures of worry and the associated symptoms of GAD have not been effective at differentiating GAD from depression (Brown et al. 1995). The poor discriminability of these questionnaire measures is consistent with the hierarchical model of anxiety and depression, which proposes that negative affect is associated with both anxiety and mood disorders (Brown et al. 1998).

**Panic Disorder with or without Agoraphobia**

Unlike GAD, panic disorder is characterized by the presence of recurrent, unexpected panic attacks and anxiety about future attacks. Although individuals with GAD may experience panic attacks, the attacks themselves are typically not the focus of their anxiety. Rather, the apprehension is often more diffuse. Patients with GAD are also more likely to experience chronic somatic symptoms rather than the discrete episodes of intense autonomic arousal associated with panic disorder. Although the ICD-10 prohibits diagnosing GAD if its symptoms occur during the course of panic disorder, the DSM-IV-TR does not impose this restriction. A patient experiencing anxiety about future panic attacks as well as excessive, uncontrollable worry about school, family, and minor matters may warrant both diagnoses. One study found that 18% of patients with a current principal diagnosis of GAD also met criteria for an additional diagnosis of panic disorder with or without agoraphobia (Brown et al. 2001a).

**OCD**

Although OCD is a highly reliable diagnostic category (kappa = 0.75; Brown et al. 2001b), the disorder’s phenomenological similarity to GAD has been noted (e.g., Craske et al. 1989). Worry and obsessions may appear similar, as might compulsions and reassurance-seeking behavior. In a review of the literature on obsessions and worry, Turner et al. (1992) concluded that existing data could not point to whether they were distinct phenomena. They noted that obsessions and worry are present to some degree in both clinical and nonclinical populations, often appear similar in form and content, are more frequent and less controllable in clinical populations, are both accompanied by negative affect, and appear to have a shared genetic vulnerability. The DSM-IV-TR offers some guidelines for differentiating obsessions and worry. The definition of OCD, for example, specifies that obsessions are not simply excessive worries about real-life problems. Rather, OCD is characterized by preoccupations that are intrusive and often ego-dystonic, or bizarre and alien to the individual (Rachman 1973). Furthermore, intrusive thoughts in OCD may elicit a phobic or panic reaction and are typically avoided or resisted, whereas worry thoughts, even if intrusive or repetitive, are typically not resisted (Steketeer and Barlow 2002). Worry and obsessions may also exhibit differences in form. Worry is a predominantly verbal/linguistic process, whereas obsessions may take the form of impulses or images.

A large-scale study of the structural relationships among disorder features supports the notion that GAD and OCD overlap significantly (Brown et al. 1998). In this study, GAD exhibited the highest degree of overlap with other DSM-IV-TR diagnosis factors, as well as significant overlap with a nonspecific negative affect factor. The OCD latent factor was most strongly correlated with the GAD factor ($r = 0.52$), a finding perhaps attributable to similarity between chronic worry and obsessions, which both may be conceptualized as excessive and/or uncontrollable cognitive processes associated with negative affect.

Despite the similarity between chronic worry and obsessions and the structural relationships between the disorder constructs, a low rate of co-occurrence has been observed between OCD and GAD in some clinical studies (Brown et al. 2001b, 1993), whereas others have reported that over 30% of adults with OCD have a lifetime history of GAD (Andrews et al. 1990, Crino and Andrews 1996). In a sample consisting of 31 patients with a principal diagnosis of OCD and 46 with a principal diagnosis of GAD, patients with GAD were more likely to describe themselves as worriers and/or worry about minor matters than were patients with OCD, and patients ultimately diagnosed with OCD were more likely to respond affirmatively to interview screening questions for obsessions and compulsions (Brown et al. 1993). In addition, patients with OCD received significantly higher scores on a self-report measure of obsessions than did patients diagnosed with GAD, although significant correlations between scores on measures of obsessions and compulsions and worry were observed. Other studies have also indicated similarities between compulsions in OCD and worry-driven behaviors in GAD. In one sample, over half of the patients with GAD reported engaging in some “corrective, preventative, or ritualistic” act in response to their worry (Craske et al. 1989). A measure of thought–action fusion, or the tendency to assume causal relationships between one’s own thoughts and the external world (Rachman 1993), has been used to differentiate obsessions from worry in an undergraduate sample, although this finding has not been replicated in a clinical sample (Coles et al. 2001). Studies on nonclinical samples have also indicated that individuals are more aware of the triggers of worry than of obsessions and that they consider obsessions less voluntary, although worry content and the presence of worry are more distressing than obsessions (Langlois et al. 2000).

Despite the shared variance between worry and obsessions and compulsions, the diagnoses can be reliably distinguished from another by trained interviewers. In a large-scale reliability study, diagnostic disagreements involving OCD were relatively uncommon; in the two disagreements involving another disorder, the other disorder involved was anxiety disorder NOS (Brown et al. 2001a). The low rate of co-occurrence of GAD and OCD and the high diagnostic reliability for OCD observed in these samples may indicate that interviewers observed features of both disorders in patients but subsumed the features of one under the principal diagnosis. This interpretation is unlikely, however, given the absence of diagnostic disagreements involving principal diagnoses of OCD and GAD. Although worry and obsessions are phenomenologically similar, this study indicates that OCD and GAD may be reliably differentiated. Nevertheless, there remains no definitive method by which to distinguish worries from obsessions.

**Hypochondriasis**

Patients with GAD often report worrying about their own health and the health of significant others. A diagnosis of hypochondriasis may be considered, however, if a patient’s
worry is predominantly about his or her health, rather than about a variety of topics. Hypochondriasis is also characterized by strong belief in conviction, even in the face of contrary evidence, that one has a physical illness. Although patients with GAD may exhibit future-oriented worry about contracting or developing a disease, they are less likely than individuals with hypochondriasis to believe that they currently have an illness.

**Anxiety Disorder Due to a Medical Condition**

Several medical conditions are associated with prominent symptoms of anxiety. Self-reported anxiety is a significant predictor of functional impairment in a variety of medical conditions, although is most common in individuals with digestive ailments (Marcus et al. 1997). Thyroid dysfunction, particularly hyperthyroidism, has long been associated with increased risk of generalized anxiety and panic attacks (Denicoff et al. 1990, Greer et al. 1973). Although the magnitude of this increased risk is unclear, practitioners may consider thyroid function testing in previously unscreened patients (Simon et al. 2002).

**Differences in Gender and Cultural Presentations**

A robust finding of epidemiological studies is that GAD is approximately twice as common among women as among men (e.g., Wittchen et al. 1994). Few studies have examined cross-cultural differences in GAD, and there has been little indication that the prevalence or expression of symptoms differs reliably between cultural groups. In the National Comorbidity Survey, race, education, income level, and urbanicity were not unique predictors of risk for GAD (Wittchen et al. 1994). Another large epidemiological study, the National Epidemiologic Survey on Alcohol and Related Conditions, found that being female, unmarried (widowed, separated, or divorced), and having low income increased risk of GAD, whereas being black, Asian, or Hispanic decreased risk (Grant et al. 2005). There is some evidence that the lower risk for GAD may be found only among younger cohorts and be more pronounced among groups with less education (Breslau et al. 2005). In a large, nonclinical sample, African Americans, Asian Americans, and Caucasians did not differ in their scores on several measures of worry severity, although there were group differences on a questionnaire examining worry in particular domains (Scott et al. 2002). African Americans reported less worry than both other groups regarding relationships, self-confidence, and work. It is possible that more culturally relevant measures of worry may tap domains not assessed by commonly used self-report measures. Several epidemiological studies have examined the prevalence of GAD in various cultural groups. Studies in non-US populations have found lifetime prevalence rates of 0.8% in Germany (Wittchen et al. 1998), 3.7% in South Africa (Bhagwanjee et al. 1998), and 3.3% in Singapore (Lim et al. 2005).

**Etiology and Pathophysiology**

Evidence from genetics, neurobiology, and psychology suggests a multifactorial etiology for GAD, consistent with Barlow’s (2000) proposed triple vulnerabilities model. This model posits that anxiety disorders result from the combination of a general biological vulnerability, a general psychological vulnerability, and a specific psychological vulnerability. Evidence for each of these vulnerabilities is discussed further below.

**Genetic Factors**

Studies examining genetic vulnerabilities for mental disorders have generally supported the notion that a shared vulnerability underlies anxiety disorders (Hettema et al. 2005). A meta-analysis of genetic epidemiology studies has also indicated that several anxiety disorders (including panic disorder, GAD, phobias, and OCD) aggregate in families and that the major source of familial risk is genetic (Hettema et al. 2001). Family and twin studies have also indicated a modest contribution of genetic factors to the development of both GAD and neuroticism. Notably, a large-scale twin study found that the genetic factors associated with neuroticism were indistinguishable from those conferring risk for GAD (Hettema et al. 2004), consistent with the high degree of overlap between neuroticism and GAD that has been observed in structural analyses (Brown et al. 1998). GAD and neuroticism shared only a modest proportion of individual environmental risk factors. Twin studies have also indicated substantial overlap in the genetic factors conferring risk for neuroticism and a variety of other internalizing disorders (Hettema et al. 2006), which is perhaps not surprising given the structural relationships observed between neuroticism and depression, GAD, social phobia, and OCD. Twin studies have also pointed to a shared genetic diathesis for depression and GAD. In a large-scale study of female twins, Kendler et al. (1992) found evidence of a completely shared genetic vulnerability for GAD and MDD. In contrast, the two disorders shared only some environmental risk factors, suggesting that nonfamilial environmental factors (e.g., stressful life events) determine whether an individual develops symptoms of depression or chronic anxiety.

Extant genetic research has focused on identifying shared genetic vulnerabilities for emotional disorders through twin studies, although researchers have begun to look more specifically at the genes associated with these disorders. Linkage studies have identified several genes that may confer risk for anxiety disorders (e.g., Thorgerirsson et al. 2003), but more studies are necessary to link particular genes with symptoms of emotional disorders.

**Neurobiological Factors**

**Autonomic Function**

An association between chronic anxiety and autonomic inflexibility, or an apparent restriction of sympathetic activation, has been demonstrated in several physiological studies (Hoehn-Saric et al. 2004, Thayer et al. 1996). Although it has been associated with a variety of emotional disorders, including panic disorder, autonomic inflexibility may be particularly relevant to GAD due to its association with the worry process (Friedman and Thayer 1998, Hoehn-Saric et al. 2004). Borkovec (1994) has proposed that worry is a verbal/linguistic process that serves to modulate the experience of anxiety and prevent the full processing of emotionally charged stimuli. In accordance with this view, psychophysiological studies have shown that worry is associated with restricted sympathetic arousal and low vagal tone.
Neurotransmitter Abnormalities

Several neurotransmitter systems have been implicated in the etiology and maintenance of GAD. Because benzodiazepines are effective in reducing some symptoms of anxiety, researchers have speculated that individuals with GAD exhibit abnormalities in benzodiazepine receptor binding and distribution. One study has found decreased binding in the left temporal lobe of patients with GAD (Tiihonen et al. 1997). Results from studies examining plasma levels of norepinephrine in patients with GAD have been equivocal (Kelly and Cooper 1998, Mathew et al. 1982). GAD has been associated, however, with blunted growth hormone response to clonidine challenge tests, which assess noradrenergic receptor sensitivity (Abelson et al. 1991). Although selective serotonin-reuptake inhibitors (SSRIs) are widely used in the treatment of GAD, there is modest evidence of serotonin abnormalities in patients with GAD. Germine et al. (1992) examined emotional response to m-chlorophenylpiperazine, a serotonin agonist, in patients with GAD and depression. The depressed patients did not exhibit behavioral changes, but those with GAD experienced increased anxiety and anger. Like other emotional disorders, GAD appears to be associated with alterations in several neurotransmitter symptoms.

Neuroromaging Studies

Few neuroimaging studies have examined patients with GAD. An early positron emission tomography (PET) study indicated hypermetabolism in the right prefrontal cortex, right posterior temporal lobe, and a portion of the left occipital lobe, and lower metabolic rates in the basal ganglia in patients with GAD compared to control participants (Wu et al. 1991). In a small structural magnetic resonance imaging (MRI) study of children and adolescents, patients with GAD exhibited increased total and right amygdala volume compared to nonanxious controls (DeBellis et al. 2000). Abnormalities in fear circuitry, particularly hyperactivation in the right amygdala, have been observed in adolescents with GAD (McClure et al. 2007). Although suggestive of structural or metabolic abnormalities in patients with GAD, most extant studies have compared individuals with GAD to normal controls, not to patients with other anxiety disorders. It remains unclear, therefore, if the aforementioned findings are specific to GAD or characteristic of all anxiety disorders.

Psychological Factors

Pathological Worry

Borkovec (1994) has proposed that worry is a verbal-linguistic attempt to avoid future negative events. Worry provides short-term relief from intense levels of anxiety by allowing individuals to escape from aversive cognitions and images but may inhibit processing of anxiety-producing stimuli. Worry, therefore, is akin to situational avoidance in panic disorder; although it alleviates short-term discomfort, it ultimately serves to maintain anxiety through negative reinforcement. For example, a student worrying about an upcoming test might think in abstract terms (e.g., “This is going to be terrible”) rather than invoke concrete images of the feared experience. Worry may prevent the complete activation of fear structures in memory, which may be necessary for long-term anxiety reduction (Borkovec and Hsu 1990, Foa and Kozak 1986). Worry may also preclude effective problem solving because worry content often skips from one topic to another without resolution of particular problems.

Perceived Lack of Control

Barlow (2002) has proposed that early experiences of uncontrollability may serve as a psychological vulnerability for emotional disorders. In studies with nonclinical samples, social psychologists have demonstrated that maintaining the illusion of control (i.e., the belief that one can affect and cope with events in one’s environment) is adaptive (Alloy and Celmants 1992, Taylor and Brown 1994, Taylor et al. 2000). Individuals with clinical disorders, including people diagnosed with anxiety disorders, sexual dysfunctions, and depression, often perceive themselves as having little control over their experiences (e.g., Cole and Turner 1993, Ladouceur et al. 1999, Weisberg et al. 2001). Patients with GAD are more likely than controls to perceive a lack of control over threatening events and to regard ambiguous information as threatening (Rapee 1991). This perceived lack of control may result from a variety of events, including trauma and insecure attachment to primary caregivers (Borkovec 1994). In patients with GAD, worry may be an ineffective attempt to assert control over uncertain future events. Intolerance of uncertainty, a construct related to perceived lack of control, has emerged as an important variable in the study of anxiety disorders (Dugas et al. 1998). Defined as the inability to accept that future negative events may occur, intolerance of uncertainty has been associated with symptoms of several anxiety disorders but is greater in individuals with GAD than in patients from a mixed anxiety disorder sample (Ladouceur et al. 1999). There is some evidence that treatment designed to specifically address intolerance of uncertainty is more efficacious than a wait-list control condition in alleviating symptoms of GAD (Ladouceur et al. 2000).

Social/Environmental Factors

Barlow’s (2000, 2002) model of the etiology of anxiety disorders posits that psychological and biological vulnerabilities may interact with stressful life events to produce clinical-level anxiety symptoms. As previously mentioned, stressful life events may play a differential role in the onset of early- and late-onset GAD (Campbell et al. 2003). Twin studies have suggested that GAD is only modestly heritable and largely determined by environmental influences (Hettema et al. 2001). Furthermore, although the genetic factors conferring risk for GAD and neuroticism overlap almost entirely, there is only modest overlap between the environmental risk factors (Hettema et al. 2004). The nature of the stressors that precipitate the onset of GAD remains unclear. In one study, 52% of individuals diagnosed with GAD reported
experiencing at least one past traumatic event (i.e., an event that would satisfy criterion A of the DSM-IV-TR definition of PTSD), whereas only 21% of nonanxious controls did, although it is unclear if the events occurred prior to the onset of the GAD (Roemer et al. 1996).

In summary, current etiological models of GAD propose that the disorder results from a combination of genetic, neurobiological, and psychological factors. Like most mental disorders, GAD is best described by a diathesis-stress model in which biological and psychological vulnerabilities interact with life stress to produce the onset of symptoms.

**Treatment**

Many patients with GAD present to their primary-care physicians (PCPs) for treatment of somatic problems, which may include headache, muscle tension, gastrointestinal problems, and fatigue (Roy-Byrne and Wagner 2004, Wittchen 2002). Unfortunately, PCPs infrequently recognize GAD and rarely prescribe psychotherapy or pharmacotherapy (Wittchen 2002), although empirically supported treatments are available.

**Somatic Treatments**

The most common pharmacological treatments for GAD include benzodiazepines, azapirones, and SSRIs. Benzodiazepines, which produce short-term sedation, muscle relaxation, and decreased physiological arousal, may provide relief from the somatic symptoms of GAD (Hoehn-Saric et al. 1988). Concerns have emerged, however, about the long-term use of benzodiazepines, which may lead to dependence (Ballenger et al. 2001). Azapirones, which include buspirone, are associated with less risk of dependence than benzodiazepines, although evidence for their efficacy in the treatment of GAD is equivocal (Davidson et al. 1999, Gammans et al. 1992). It is also noteworthy that the use of fast-acting drugs such as benzodiazepines and azapirones may be contraindicated by cognitive-behavioral approaches to GAD, which emphasize the importance of tolerating rather than avoiding the experience of anxiety.

Numerous antidepressants have been evaluated in the treatment of GAD. Two older drugs, trazodone and imipramine, were shown to be as effective as diazepam, although were less effective at alleviating somatic symptoms than psychological symptoms (Rickels et al. 1993). Several trials with newer antidepressants, including SSRIs and serotonin and norepinephrine-reuptake inhibitors (SNRIs), have produced promising findings. In a placebo-controlled trial of paroxetine, an SSRI, 62% and 68% of patients receiving 20 and 40 mg of paroxetine experienced significant symptom reduction, compared to only 46% in the placebo group (Rickels et al. 2003). Venlafaxine, an SNRI, was the first antidepressant approved by the Federal Drug Administration (FDA) for the treatment of GAD based on the results of several large, placebo-controlled trials (Sheehan 1999, Davidson et al. 1999). Unfortunately, there have been no large trials comparing the efficacy of two or more antidepressants in the treatment of GAD.

**Psychosocial Treatments**

Cognitive-behavioral conceptualizations of GAD assume that individuals’ thoughts and behaviors play a primary role in maintaining their symptoms. Several randomized controlled trials have examined the efficacy of cognitive-behavioral treatment (CBT) packages in individuals with GAD. In general, these studies have indicated that CBT for GAD, although it results in clinically significant improvement, is associated with lower rates of high end-state functioning than CBT for panic disorder (Barlow et al. 2000). Studies typically examine the effects of a CBT package rather than individual components of treatment. Most CBT packages consist of psychoeducation about the nature of anxiety, symptom monitoring, relaxation training, exposure (imaginal and in vivo), and cognitive restructuring. To date, the majority of treatment trials have compared CBT to no-treatment control groups. Those that have compared two or more active treatments have often found no clear evidence of differential efficacy (e.g., Barlow et al. 1992, Borkovec and Mathews 1988), although Borkovec and Costello (1993) found that CBT was associated with higher end-state functioning at follow-up than either applied relaxation training or nondirective treatment. Other studies have indicated that CBT is no more efficacious than nondirective treatments (e.g., Blowers et al. 1987). In an effort to identify active components of treatment, Borkovec et al. (2002) compared groups receiving either applied relaxation or self-control desensitization (i.e., rehearsing relaxation and coping statements in imaginal exercises), cognitive therapy, or a combination of these elements. No group differences were found, suggesting that each component was beneficial. Nevertheless, by 24 months posttreatment, only 52% of individuals in the cognitive therapy condition, 48% in the relaxation/self-control desensitization condition, and 38% in the combined condition met criteria for high end-state functioning.

In a recent meta-analysis of CBT for GAD, Mitte (2005) found that CBT was more efficacious than control conditions, yielding medium to large effect sizes when compared to pill or psychological placebo. In studies directly comparing CBT with pharmacotherapy (most often benzodiazepines), there was no difference in effect sizes between the two treatments. In contrast, an indirect comparison of CBT and pharmacotherapy (which included studies comparing each treatment to a control condition) suggested the superiority of drug treatment. However, attrition was lower for individuals receiving CBT (9%) than for those receiving pharmacotherapy (25%). Currently, neither mode of treatment is unequivocally superior to the other, and there are no large trials comparing combination therapy to either CBT or pharmacotherapy alone. Although elements of CBT packages vary, some common CBT components are discussed below.

**Self-Monitoring**

Self-monitoring of symptoms is a component of most cognitive-behavioral approaches. Data obtained by the patient are useful for conducting functional analyses of the patient’s anxiety and worry episodes (i.e., determining the situational, psychological, and behavioral antecedents of worry; the methods used by the patient to alleviate anxiety; and the consequences of these actions). An example of a weekly record of mood and anxiety is shown as Figure 73–2. Routine self-monitoring not only allows the patient to gain experience observing and describing his or her symptoms, but also allows the clinician to track the patient’s progress over time. Self-monitoring forms may be tailored to the individual...
patient and used to track a variety of behaviors (e.g., benzodiazepine use and reassurance-seeking behavior).

**Psychoeducation**

The nature of anxiety is discussed in order to normalize the patient’s experience and distinguish between adaptive and maladaptive anxiety. The clinician and patient discuss biological and psychological factors related to the experience of anxiety, as well as the interaction between the three components of anxiety (i.e., thoughts, physical sensations, and behaviors). The concept of avoidance, or an individual’s refusal or hesitation to enter situations or tolerate certain experiences, is introduced, and the clinician explains the role of avoidance in perpetuating the cycle of maladaptive anxiety. The clinician discusses worry as an avoidance strategy that prevents adequate processing of anxiety-provoking stimuli.

**Cognitive Restructuring**

Cognitive therapy as outlined by Beck and colleagues (1985) is a component of many cognitive-behavioral protocols. Cognitive therapy entails the elicitation of automatic thoughts that serve to maintain patients’ anxiety. After automatic thoughts are identified, the therapist and patient work together to evaluate the accuracy and utility of these thoughts. For example, anxious patients often think catastrophically (i.e., focus on the worst possible scenario) and overestimate the probability of negative events. Once the distorted thoughts are identified, patients develop alternative, rational thoughts. For example, a woman with GAD may assume that her husband has gotten into a car accident if he does not arrive home on time. An alternative thought may take into consideration her husband’s long commute, the heavy traffic, or the possibility that he stayed late at work. Focusing on distorted cognitions may seem particularly relevant to the treatment of excessive and uncontrollable worry. As discussed below, however, some have questioned the utility of traditional cognitive restructuring in the treatment of GAD.

**Exposure**

Situational exposures are an important component of CBTs for specific phobias, social phobias, OCD, and PTSD. Although GAD patients may also avoid anxiety-provoking situations, their primary mode of avoidance is worry (Borkovec 1994). Due to the difficulty of planning situational exposures in the absence of a clear phobic target, several CBT protocols for GAD (e.g., Craske et al. 2000) include worry exposures, during which the patient undergoes graded, imaginal exposures to the worst possible outcomes of various worries. During these exposures, the patient holds distressing images in mind for at least 25–30 minutes and then generates alternatives to the worst possible outcome. Throughout the exposure, the patient is asked to provide subjective ratings of their anxiety. After the worry exposure technique is introduced in session, the patient is assigned exposure homework throughout treatment. Even if the patient denies engaging in overt situational avoidance, the clinician should also assess for subtle behavioral avoidance. Patients, for example, may restrict their range of experience due to their excessive worry. Roemer et al. (2002) suggest asking patients what activities they would engage in if they worried less. Clinicians must work with patients to gradually eliminate these forms of avoidance, with the aim of demonstrating that they do not serve any protective function. Because GAD is so frequently comorbid with depression, some treatment protocols also include pleasant events scheduling, an approach intended to increase engagement in enjoyable activities.

**Relaxation Training**

A traditional component of many anxiety treatment protocols is progressive muscle relaxation (PMR), as described by Bernstein and Borkovec (1973). PMR entails the tensing and relaxing of various muscle groups, with the goal of alleviating physiological symptoms of anxiety. A full, 16-muscle-group PMR session typically lasts 30 minutes, although time spent on PMR is reduced over the course of treatment.
in order to make the exercise more “portable.” PMR may be particularly useful in addressing anxiety-related muscle tension. Notably, PMR has also been used in the treatment of IBS, a condition commonly found among GAD patients (Toner et al. 2000).

**Worry Behavior Prevention**

As previously mentioned, many patients with GAD engage in corrective, preventative, or ritualistic behaviors that resemble the compulsions observed in OCD (Craske et al. 1989). These worry behaviors, which may include frequent telephone calls to family members for reassurance and avoidance of negative news stories, may result in the temporary reduction of anxiety, but also in its long-term maintenance. Once the patient and therapist have identified and monitored these behaviors, the patient will practice refraining from them and observing the consequences of behavior prevention. Often the patient’s predictions regarding response prevention are inconsistent with the outcome of the exercise (i.e., the feared outcome does not occur). Gradual reduction of benzodiazepine use may be a target of CBT for anxiety disorders, as some patients use these drugs as avoidance strategies.

**Additional Components**

Because patients with GAD often report feeling overwhelmed by their obligations, the therapist may introduce basic time management skills (e.g., delegating responsibilities, saying “no” to additional obligations, and adhering to an agenda). Training in problem solving may be included if patients tend to view problems catastrophically or if they have difficulty generating solutions to problems. Although individuals with GAD do not exhibit deficits in problem-solving skills, they may have more difficulty applying these skills than those with less severe worry (Dugas et al. 1998, Ladouceur et al. 1998). Approaches to problem-solving training vary, although Meichenbaum recommends teaching patients to conceptualize problems in specific terms and break them down into small, manageable segments (e.g., Meichenbaum and Jaremko 1983). Once the problem is defined, the patient is taught to brainstorm possible solutions, even those that initially sound unreasonable. Once a list of potential solutions has been generated, the patient selects and acts on the best possible option. These techniques allow patients to focus on real problems rather than imagined catastrophes and prompt them to think differently about difficult situations in their lives.

**Recent Developments in Psychosocial Treatments**

Newer psychosocial treatments for GAD have integrated acceptance and mindfulness approaches into traditional CBT (Orsillo et al. 2003). These approaches, which include Hayes et al.’s (1999) Acceptance and Commitment Therapy, posit that individuals’ efforts to control their internal experience often backfire, resulting in increased anxiety and dissatisfaction. Hayes argues that individuals’ reluctance or unwillingness to remain “in contact” with their internal experience (thoughts, sensations, and emotions) may underlie many forms of psychopathology. Newer approaches to GAD treatment also draw from Wells’ metacognitive theory, which hypothesizes that individuals with GAD tend to appraise their worry as more threatening and uncontrollable than do normal controls (and yet, paradoxically, believe that it is functional and adaptive) (Borkovec et al. 1999, Wells 2002). Notably, cognitive restructuring may be incompatible with these approaches, which emphasize the acceptance of anxious thoughts and place less importance on active attempts to change them. Elements of acceptance-based approaches may include experiential exercises, mindfulness training, identification of the patient’s overriding values, and exploration of the incompatibility of experiential avoidance with these values (e.g., Orsillo et al. 2001). The efficacy of these newer approaches compared to extant CBT is yet to be determined by controlled trials (Figure 73–3).

**Treatment of Special Populations**

**Children**

Because GAD was not considered a childhood/adolescent disorder prior to the publication of DSM-IV, there is a paucity of treatment trials in this population. The precursor to childhood GAD in DSM-III and DSM-III-R was overanxious disorder, a category prone to overdiagnosis (e.g., Beidel et al. 1996) and low diagnostic reliability relative to other anxiety disorders (e.g., Silverman and Eisen 1992). Several small studies have demonstrated the efficacy of CBT in the treatment of overanxious disorder or GAD (e.g., Eisen and Silverman 1998, Kane and Kendall 1989). In randomized controlled trials with mixed anxiety samples, CBT has produced greater symptom reduction than wait-list control conditions immediately posttreatment and at long-term follow-up (Kendall 1994, Kendall et al. 1997, Flannery-Schroeder and Kendall 2000), although additional research is needed to assess differential treatment response across anxiety disorders. Other promising interventions incorporate family-management components into existing CBT protocols (e.g., Barrett et al. 1996). Few studies have examined the use of pharmacotherapy in childhood GAD, although one small,
placebo-controlled trial has supported the efficacy of sertraline (50 mg) in children and adolescents (ages 5–17 years) (Rynn et al. 2001).

**Elderly**

Although the most recent data from the NCS-R suggest that GAD is not prevalent among older individuals (Kessler et al. 2005b), it has been estimated that 17% of elderly men and 21.5% of elderly women have sufficiently severe symptoms to warrant treatment (Himmelgarn and Murrell 1984). Moreover, a larger proportion of elderly individuals may not meet full criteria for GAD but, nevertheless, experience clinically significant distress or impairment as a result of their symptoms (Diefenbach et al. 2003). At least one randomized controlled trial has indicated that CBT is efficacious relative to no treatment in older adults, although only a minority of patients receiving CBT (45%) were classified as responders and those receiving CBT did not return to their premorbid level of functioning following treatment (Stanley et al. 2003).

**Treatment Refractory Patients**

Randomized controlled trials of CBT and pharmacotherapy have identified several factors, predicting poor outcome in the treatment of GAD. Patients with interpersonal problems, defined as vindictive, intrusive, and domineering relationships, demonstrated poorer outcomes immediately posttreatment and at 2-year follow-up in CBT trial (Borkovec et al. 2002). Comorbidity has been associated with poorer outcomes among untreated GAD patients (Yonkers et al. 2003), underscoring the importance of including comorbid patients in treatment trials and reporting both initial and posttreatment levels of comorbidity. There is evidence that comorbidity decreases during psychosocial treatment of GAD (e.g., Ladouceur et al. 2000), although additional research is necessary to understand the relationship between pretreatment comorbidity and treatment outcome.

**Special Factors Influencing Treatment**

Patients’ belief in the functionality of worry may serve as a barrier to treatment progress, although this hypothesis requires empirical examination. Individuals with GAD often believe that their worry will help them prepare for, or help them avoid, future negative events (Borkovec and Roemer 1995), despite evidence to the contrary (Borkovec et al. 1999). Because individuals with GAD often fear low-frequency events, their worry may be reinforced by the non-occurrence of their feared outcomes (Borkovec et al. 1999). Effective treatment of GAD requires that patients understand that their worry, although it may feel functional, is not an effective problem-solving strategy.

**Case Vignette 1**

Cindy was a 23-year-old, single Caucasian woman who had recently graduated from college. She reported that she was a lifelong “worrier” but that her anxiety had gotten worse after graduation. Cindy had a history of panic disorder, which had been successfully treated 3 years previously, multiple episodes of depression, and IBS. Although she had visited several gastroenterologists in the previous year, her bowel symptoms and pervasive anxiety persisted. Cindy reported frequent “breakdowns,” during which she would become overwhelmed by daily tasks and begin crying uncontrollably. She worried frequently about her own health and became anxious when she saw news stories about epidemics. In addition, she was preoccupied with the future and had imagined various bleak possibilities (e.g., failing to “live up to [her] potential” and “wasting” her education). She was dissatisfied with her job and frequently went outside during the day to smoke cigarettes and pace. Cindy also experienced frequent muscle tension and had signed up for a yoga class but was too “impatient” to attend regularly. She noted that she could only relax when she was home watching television. She said her ideal day was one during which she had no obligations. Although her family was supportive of her, they were becoming increasingly frustrated by her tearful phone calls. Once a very social woman, Cindy had become increasingly withdrawn, insisting that she was unable to relax when she went out with friends. Her gastrointestinal symptoms had gradually worsened, and she had missed several days of work due to diarrhea. She was referred to an anxiety clinic by her gastroenterologist and was treated with a combination of sertraline and CBT. She attended approximately 20 sessions of CBT, which included thought monitoring and cognitive reappraisal, relaxation training, and worry exposure. Additional situational exposures (e.g., riding the subway) were included to address Cindy’s avoidance of situations in which she might experience IBS symptoms. At posttreatment, Cindy demonstrated significant improvements on questionnaire measures of GAD symptoms, as well as fewer crying spells, more frequent social contact, and less reassurance seeking.

**Case Vignette 2**

Michael was a 67-year-old Caucasian man who sought treatment after decades of excessive anxiety. He described himself as “high-strung” but noted that this quality was an asset during his career in business. Following his retirement, however, he found himself unable to relax. Michael often awoke several hours early and was unable to return to sleep. He kept a “mental checklist” of tasks he wished to complete that day but often procrastinated. Consequently, his checklist became longer and more overwhelming. Michael’s anxiety led to frequent interpersonal difficulties, particularly with romantic partners. Married and divorced twice, Michael acknowledged that he was “hard to live with” as a result of his intense irritability. His current partner often complained that he was so preoccupied with his worries that he no longer listened to her when she spoke. Michael initially had difficulty describing the content of his worry. Through self-monitoring, however, he discovered that his primary areas of concern were minor matters and personal finances. He frequently worried about trivial errands and stated that financial worries were on his mind “all day long,” even though he was financially secure. Michael sought treatment after coming to the realization that he was “wasting” his retirement by worrying excessively. He was reluctant to take medication and therefore sought CBT for his anxiety. Treatment included standard components of CBT for GAD (e.g., cognitive reappraisal, worry exposure, and problem-solving training), as well as mindfulness training to help Michael focus his attention on the present rather than on future-oriented worries.
Summary

Once a residual category in the DSM, GAD did not achieve the status of a full disorder until the publication of DSM-III-R in 1987. Since then, its definition has been revised substantially and now consists of excessive and uncontrollable worry accompanied by symptoms associated with negative affect. In light of the disorder’s poor diagnostic reliability, many revisions to the diagnostic criteria have been proposed. As it is currently defined, GAD is associated with high rates of comorbidity and substantial overlap with depression and other anxiety disorders. Like most mental disorders, the etiology of GAD is complex. There is evidence that GAD is at least partially heritable and associated with abnormalities in neurotransmitter systems and autonomic function, as well as psychological vulnerabilities. Although several empirically supported treatments for GAD have been identified (including pharmacological and psychosocial approaches), treatment for GAD has lagged behind that of some other anxiety disorders.

Introduction

The somatoform disorders are a major diagnostic class in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000) that groups together conditions characterized by physical symptoms suggestive of, but not fully explained by, a general medical condition or the direct effects of a substance. In this class, symptoms are not intentionally produced and are not attributable to another mental disorder. To warrant a diagnosis, symptoms must be clinically significant in terms of causing distress or impairment in important areas of functioning. The disorders included in this class are somatization disorder, undifferentiated somatoform disorder, conversion disorder, pain disorder, hypochondriasis, body dysmorphic disorder, and somatoform disorder not otherwise specified (NOS).

Historically, the somatoform disorders were first officially grouped together in the Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) (American Psychiatric Association 1980). The class was characterized by the presence of physical (somatic) symptoms that were not fully explained by physical conditions. In DSM-IV-TR, the phrase “general medical condition or the direct effects of a substance” corresponds to the “physical disorders” of DSM-III and the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) (American Psychiatric Association 1987). By definition, a general medical condition includes any medical condition not considered mental or psychiatric. Substances include any drugs of abuse (including alcohol), medications, or toxins. By “direct effect” we mean the actual physiological effects of a substance, such as intoxication or withdrawal, rather than indirect effects, such as the psychosocial consequences of abuse or dependence. This cumbersome terminology was adopted to avoid the designation of certain conditions as physical, organic, or biological, which could be interpreted to imply that such factors did not contribute to conditions identified as mental, functional, or psychiatric. In essence, general medical condition refers to any nonpsychiatric medical condition, which includes any medical condition not listed in the mental disorders section of the International Statistical Classification of Diseases and Related Health Problems, 10th Revision (ICD-10) (World Health Organization 1992). Examples include virtually all infectious and parasitic, endocrine, nutritional, metabolic, immunity, and congenital disorders of any organ system (including the nervous system). DSM-III and DSM-III-R (American Psychiatric Association 1987) required that “no demonstrable organic findings or known physiologic mechanisms” be present, whereas DSM-IV-TR specifies only that the physical symptoms not be fully accounted for by a general medical condition or the direct effects of a substance.

The somatoform disorders class was created for clinical utility, not on the basis of an assumed common etiology or mechanism. In DSM-IV-TR terms, it was designed to facilitate the differential diagnosis of conditions in which the first diagnostic concern is the need to “exclude occult general...
Many criticisms of the somatoform disorder category have been raised, and the banding of the class with the assignment of several of the disorders to other diagnostic classes has been considered (Hales 1996, Mayou et al. 2005). As summarized by Murphy (1990), criticisms include contents that because the category is delineated on the basis of presenting symptoms, it is “superficial”, that the individual disorders are not qualitatively distinct from one another or from “normality” and hence would be better described dimensionally rather than differentiated categorically, that the disorders are derived from hospital rather than community- or primary care-based populations, and, perhaps the most serious challenge, that the grouping “gives the spurious impression of understanding.” On the other hand, proponents maintain that the somatoform grouping represents a major advance over previous systems and that segregation of such disorders into a class has helped clarify the conceptualization of understanding.” On the other hand, proponents maintain that the somatoform grouping represents a major advance over previous systems and that segregation of such disorders into a class has helped clarify the conceptualization of “mind–body” distinction, promoted greater consistency of understanding. In DSM-IV-TR, such elements are required only in the context of fear or anxious foreboding. In general, there is a lack of a consistent physical focus. In mood disorders in other diagnostic classes. However, in such instances, the overriding focus is on the primary symptom complex (i.e., anxiety, mood, or psychotic symptoms) rather than the physical symptoms. In panic disorder and in generalized anxiety disorder, physical symptoms such as chest pain, shortness of breath, palpitations, sweating, and tremulousness may occur. However, such somatic symptoms occur only in the context of fear or anxious foreboding. In general, there is a lack of a consistent physical focus. In mood disorders such as atypical depression, physical symptoms are common, but they are not necessarily consistent with the primary symptom complex.

As shown in Figure 74–1, after it is determined that physical symptoms are not fully explained by a general medical condition or the direct effect of a substance, somatoform disorders must be differentiated from other mental conditions with physical symptoms.

In contrast to malingering and factitious disorder, symptoms in somatoform disorders are not under voluntary control, that is, they are not intentionally produced or feigned. Determination of intentionality may be difficult and must be inferred from the context in which symptoms present. Somatic symptoms may also be involved in disorders in other diagnostic classes. However, in such instances, the overriding focus is on the primary symptom complex (i.e., anxiety, mood, or psychotic symptoms) rather than the physical symptoms. In panic disorder and in generalized anxiety disorder, physical symptoms such as chest pain, shortness of breath, palpitations, sweating, and tremulousness may occur. However, such somatic symptoms occur only in the context of fear or anxious foreboding. In general, there is a lack of a consistent physical focus. In mood disorders such as atypical depression, physical symptoms are common, but they are not necessarily consistent with the primary symptom complex.

The somatoform disorder concept should be distinguished from traditional concepts of “psychosomatic illness” and “somatization.” The psychosomatic illnesses involved structural or physiological changes hypothesized as deriving from psychological factors. In the DSM-III, DSM-III-R, and DSM-IV-TR somatoform disorders, such objective changes are generally not evident. The “classic” psychosomatic illnesses of Alexander (1950) included bronchial asthma, ulcerative colitis, thyrotoxicosis, essential hypertension, rheumatoid arthritis, neurodermatitis, and peptic ulcer. In DSM-IV-TR, most of these illnesses would be diagnosed as a general medical condition on Axis III, and in some cases with an additional designation of psychological factors affecting medical condition on Axis I. By definition, the diagnosis of “psychological factors affecting medical condition” is not a psychiatric disorder, but it is included in DSM-IV-TR in the section for other conditions that may be a focus of clinical attention; it involves the presence of one or more specific psychological or behavioral factors that adversely affect a general medical condition.

The descriptive use of the term “somatization” in somatization disorder is not to be confused with theories that generally postulate a somatic expression of psychological distress (Lipowski 1988, Kellner 1990, Malt 1991). Steckel et al. (1943), who coined the term, defined somatization in 1943 as the process of a “bodily disorder” occurring as the expression of a “deep-seated neurosis.” However, as argued by Kellner (1990), “empirical studies … suggest that there is no single theory that can adequately explain somatization, which is not only multifactorially determined but is an exceedingly complex phenomenon.” Furthermore, treatment strategies derived from somatization theories have not proven effective. For example, the postulation that patients with somatoform disorders are alexithymic, that is, are unable to process emotions and psychological conflicts verbally and therefore do so somatically, suggested that teaching such patients to “appreciate” and “verbalize” their emotions would circumvent the need to “somatize” them. Such treatment approaches have been ineffective (Cloninger 1987).

**Differential Diagnosis**

As shown in Figure 74–1, after it is determined that physical symptoms are not fully explained by a general medical condition or the direct effect of a substance, somatoform disorders must be differentiated from other mental conditions with physical symptoms.

In contrast to malingering and factitious disorder, symptoms in somatoform disorders are not under voluntary control, that is, they are not intentionally produced or feigned. Determination of intentionality may be difficult and must be inferred from the context in which symptoms present. Somatic symptoms may also be involved in disorders in other diagnostic classes. However, in such instances, the overriding focus is on the primary symptom complex (i.e., anxiety, mood, or psychotic symptoms) rather than the physical symptoms. In panic disorder and in generalized anxiety disorder, physical symptoms such as chest pain, shortness of breath, palpitations, sweating, and tremulousness may occur. However, such somatic symptoms occur only in the context of fear or anxious foreboding. In general, there is a lack of a consistent physical focus. In mood disorders such as atypical depression, physical symptoms are common, but they are not necessarily consistent with the primary symptom complex.
Figure 74-1 Somatic symptom diagnostic exploration and treatment algorithm. Differential diagnosis of clinically significant physical symptoms. Shadowed boxes represent diagnostic categories. GMC, general medical condition.
disorders (particularly major depressive disorder) and in schizophrenia and other psychotic disorders, somatic preoccupations, fears, and even delusions and false perceptions may be evident. In the mood disorders, these are generally mood congruent (e.g., “I’m so worthless not even my organs work anymore”), whereas in the psychoses, bizarre and mood-incongruent beliefs are typical (e.g., “Half of my brain was removed by psychic neurosurgery”).

**Differentiation Among the Various Somatoform Disorders**

Whereas it is assumed that the specific disorders in the somatoform grouping are heterogeneous in terms of pathogenesis and pathophysiology, they are also phenomenologically diverse (see Figure 74–1). In somatization disorder, undifferentiated somatoform disorder, conversion disorder, and pain disorder, the focus is on the physical complaints themselves, and thus on perceptions. In hypochondriasis and body dysmorphic disorder, emphasis is on physically related preoccupations or fears, and thus on cognitions. Somatization disorder and, to a lesser extent, undifferentiated somatoform disorder are characterized by multiple symptoms of different types; conversion disorder, pain disorder, hypochondriasis, and body dysmorphic disorder are defined on the basis of a single symptom or a few symptoms of a certain type (see Figure 74–1). Whereas somatization disorder, undifferentiated somatoform disorder, and hypochondriasis are, by definition, at least 6 months in duration, conversion disorder, pain disorder, body dysmorphic disorder, and somatoform disorder NOS may be of short duration as long as they are associated with clinically significant distress or impairment.

**Epidemiology**

In view of the vicissitudes of diagnostic approaches and the recency of the current somatoform disorder grouping, it is not surprising that estimates of the frequency of this group of disorders in the general population as well as in clinical settings are inconsistent if not nonexistent. Yet, existing data seem to indicate that such problems are indeed common and account for a major proportion of clinical services, especially in primary care settings. A World Health Organization study reported ICD-10 diagnoses of hypochondriasis in nearly 1% and of somatization disorder in nearly 3% of patients in primary care clinics in 14 countries (Ormel et al. 1994). Another study using primary care sites found 14% of 1,000 patients to be suffering from some somatoform disorder: 8% with “multisomatoform disorder” (see the undifferentiated somatoform disorder section), 4% with somatoform disorder NOS, 2% with hypochondriasis, and 1% with somatoform pain disorder (Spitzer et al. 1994).

Considering prevalence in nonclinic, community populations, Escobar et al. (1989) reported that nearly 20% of community respondents in Puerto Rico and 4.4% of comparable non-Hispanic Los Angeles residents fulfilled criteria for an “abridged somatization disorder,” a construct with a lower threshold than somatization disorder that would generally correspond to a DSM-IV-TR diagnosis of either undifferentiated somatoform disorder or somatoform disorder NOS. In the Epidemiological Catchment Area community study (Robins et al. 1984), a low estimate of the frequency of somatization disorder (0.06–0.6%) was reported. Methodological problems may have led to a falsely low rate, as discussed in the somatization disorder section. Other studies have estimated much greater frequency, at least among women (Table 74–1).

In consideration of the substantial frequency of somatoform disorders in nonpsychiatric settings, instruments have been designed to aid primary care physicians in diagnosing psychiatric conditions. The Primary Care Evaluation of Mental Disorders (PRIME-MD) (Spitzer et al. 1994) includes somatoform items in its screening questionnaire and in its physician education guide. The DSM-IV Primary Care Edition (DSM-IV-PC) includes an “unexplained physical symptoms” algorithm among the nine it included to address the most common psychiatric symptom groups presenting in primary care settings (American Psychiatric Association 1995).

The epidemiology of the specific somatoform disorders is discussed individually in the following sections.

**Treatment**

Whereas specific somatoform disorders indicate specific treatment approaches, some general guidelines apply to the somatoform disorders as a whole (Figure 74–2 and Table 74–2). By reorganizing and synthesizing the recommendations of Stoudemire (1988) and Kellner (1991) into three goals and three general strategies, the therapeutic goals include (1) as an overriding goal, prevention of the adoption of the sick role and chronic invalidism, (2) minimization of unnecessary costs and complications by avoiding warranted hospitalizations, diagnostic and treatment procedures, and medications (especially those of an addictive potential), and (3) effective treatment of comorbid psychiatric disorders, such as depressive and anxiety syndromes. The three general treatment strategies include (1) consistent treatment, generally by the same physician, with careful coordination if multiple physicians are involved, (2) supportive office visits, scheduled at regular intervals rather than in response to symptoms, and (3) a gradual shift in focus from symptoms to an emphasis on personal and interpersonal problems.

**SOMATIZATION DISORDER**

**Definition and Diagnostic Features**

As defined in DSM-IV-TR, somatization disorder is a polysymptomatic somatoform disorder characterized by multiple recurring pains and gastrointestinal, sexual, and pseudoneurological symptoms occurring for a period of years with onset before age 30 years. The physical complaints are not intentionally produced and are not fully explained by a general medical condition or the direct effects of a substance. To warrant diagnosis, they must result in medical attention or significant impairment in social, occupational, or other important areas of functioning.

The concept and criteria for somatization disorder (historically referred to as hysteria or Briquet’s syndrome) embraced by DSM-IV-TR are the distillation of a long and convoluted struggle to describe this complex, multifaceted syndrome (Martin 1988). As reviewed by Veith (1965), the origins of the concept can be traced to descriptions in the medical literature of the pre-Hippocratic Egyptians, who attributed otherwise unexplained physical symptoms to peregrinations of the uterus; this hypothesis probably

derived from observations that such presentations were predominantly seen in women with onset during the reproductive years. In the 5th century AD, the Hippocratic literature formalized the concept, adopting the term *hysteria* from the Greek word for uterus. In time, belief in a uterine cause was abandoned, but use of the term hysteria continued.

In the mid-19th century, Paul Briquet (1859) adopted the term hysteria for the syndrome he described in his monograph, *Traité Clinique et Thérapeutique à l’Hystérie*, as characterized by dramatic and excessive medical complaints without evidence of an organic cause. Ultimately, such a description would constitute the basis for somatization disorder, yet the medical complaint aspect of hysteria was overshadowed for many years by psychodynamic interpretations originating with observations by Breuer and Freud (1955). In fact, much of Freud’s theory of the unconscious can be traced to his work with hysteria. According to psychodynamic theory, “psychic energy” was converted into physical symptoms, thereby the term *conversion*. Although conversion symptoms were eventually reserved for pseudoneurological complaints, the more general term somatization came to be used for any body symptoms explained as an expression of a neurosis (Lipowski 1988, Steckel et al. 1943).

In time, the physical complaint aspect of hysteria was de-emphasized, with increased attention to intrapsychic, personality, or characterological features of hysteria. Meanwhile, in lay usage, hysteria came to signify excessive or histrionic emotional displays regardless of whether physical symptoms were involved. By the 1950s, the meaning had become so diffuse that the term hysteria, as attacked by Chodoff and Lyons (1958), had at least five connotations, only one of which related to physical complaints.

In 1951, Purtell et al. (1951) resurrected Briquet’s formulation of a syndrome characterized by multiple medically unexplained somatic complaints, adding a quantitative perspective that required a given number of symptoms from a specified list for a diagnosis. This approach was refined in 1962 by Perley and Guze (1962) and again in 1972 by Feighner et al. (1972), who included hysteria among the 13 psychiatric diagnoses “canonized” as sufficiently studied to be considered valid and reliable psychiatric disorders. As

summarized by Barsky (1989), the validity, reliability, and internal consistency of the Feighner criteria for hysteria were supported in clinical, epidemiological, and follow-up studies. In particular, the syndrome was stable, with an 80–90% probability that 6–8 years after the diagnosis was made the clinical picture would be essentially the same and no new medical or mental disorder would develop as an explanation for the original complaints.

Unfortunately, although feasible in research settings, the Feighner hysteria criteria were cumbersome clinically. Twenty-five medically unexplained symptoms from a specified list of 59 symptoms organized into 10 groups were required for a “definite” diagnosis, 20 for a “probable” diagnosis. Dissemination to different functions and organ systems was considered an essential aspect of the syndrome, a diagnosis requiring symptoms from 9 of the 10 groups.

**Somatization Disorder**

- A history of many physical complaints beginning before age 30 years that occur over a period of several years and result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning.

- Each of the following criteria must have been met, with individual symptoms occurring at any time during the course of the disturbance:
  1. **four pain symptoms**: a history of pain related to at least four different sites or functions (e.g., head, abdomen, back, joints, extremities, chest, rectum, during menstruation, during sexual intercourse, or during urination)
  2. **two gastrointestinal symptoms**: a history of at least two gastrointestinal symptoms other than pain (e.g., nausea, bloating, vomiting other than during pregnancy, diarrhea, or intolerance of several different foods)
  3. **one sexual symptom**: a history of at least one sexual or reproductive symptom other than pain (e.g., sexual indifference, erectile or ejaculatory dysfunction, irregular menses, excessive menstrual bleeding, vomiting throughout pregnancy)
  4. **one pseudoneurological symptom**: a history of at least one symptom or deficit suggesting a neurological condition not limited to pain (conversion symptoms such as impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia, urinary retention, hallucinations, loss of touch or pain sensation, double vision, blindness, deafness, seizures; dissociative symptoms such as amnesia; or loss of consciousness other than fainting)

- Either (1) or (2):
  1. after appropriate investigation, each of the symptoms in criterion B cannot be fully explained by a known general medical condition or the direct effects of a substance (e.g., a drug of abuse, a medication)
  2. when there is a related general medical condition, the physical complaints or resulting social or occupational impairment is in excess of what would be expected from the history, physical examination, or laboratory findings

- The symptoms are not intentionally produced or feigned (as in factitious disorder or malingering).
DSM-I and DSM-II mentioned only conversion and dissociative reactions (hysterical neuroses: conversion and dissociative types in DSM-II), virtually ignoring a polysymptomatic disorder. ICD-9 listed somatization disorder and Briquet's disorder under other neurotic disorders. DSM-III recognized the need for inclusion of the syndrome characterized in the Feighner criteria but sought to make the diagnosis more usable. Somatization disorder was the term coined to escape the pejorative connotation of hysteria, yet avoiding the use of eponyms such as Briquet's syndrome. It also attempted to simplify the criteria of Feighner and colleagues by reducing the required number of symptoms to 14 in women and 12 (to prevent a possible sex bias) in men, from a list of 37 potential symptoms, and abolishing the requirement that symptoms came from multiple symptom groups. Whereas the Feighner criteria approach and its predecessors included anxiety and depressive symptoms, DSM-III did not, allowing diagnoses of comorbid anxiety and mood disorders. DSM-III-R incorporated minor changes, including elimination of the sex differential; it required 13 symptoms in both men and women and shortened the list of potential symptoms to 35.

Despite such efforts to simplify, the somatization disorder construct remained cumbersome, which undoubtedly contributed to underuse (Cloninger 1996). As a result, a new diagnostic algorithm was developed by Cloninger and colleagues from a reanalysis of an existing data set requiring four pain, two nonpain gastrointestinal, one sexual or reproductive, and one pseudoneurological symptom (either conversion or dissociative) (Cloninger and Yutzy 1993, Yutzy et al. 1992). In a multisite field trial study, these criteria were shown to identify a syndrome with good correspondence to hysteria as defined by Feighner and colleagues (because of demonstrated reliability and validity of the “diagnostic gold standard”) (Yutzy et al. 1995), as well as with DSM-III and DSM-III-R criteria. The ICD-10 also includes somatization disorder within a somatoform disorder grouping. However, in addition to multiple unexplained somatic symptoms, ICD-10 requires “persistent refusal to accept medical reassurance that there is no adequate physical cause for the physical symptoms.” Attributable in part to this requirement, DSM-IV and (TR/2000), Feighner, DSM-III, and DSM-III-R criteria all showed poor agreement with the ICD-10 criteria in the multisite field trial (Yutzy et al. 1995).

Changes in the diagnosis for DSM-IV-TR appeared to have facilitated a somewhat wider acceptance. Unfortunately, a number of problems with the diagnosis have remained, including the diagnostic complexity of the criteria set; the fact that the term “somatization” has acquired a pejorative connotation, a tendency for clinicians to diagnose more readily treatable symptoms such as anxiety and depressive syndromes without considering the underlying illness, and the fact that authorization and reimbursement for treatment of this chronic condition are often challenged or denied. It is relatively easier to obtain approval for an intervention on the basis of major depressive disorder, for example, than on the basis of a disorder that is much more likely to be poorly understood by case reviewers.

Thus, whereas somatization disorder as currently defined in DSM-IV-TR is not entirely equivalent to the many previous definitions, it has a common conceptual core and appears to identify populations of patients similar to those defined by the Purcell-Robins, Perley–Guze, DSM-III, and DSM-III-R criteria. Thus, subsequent discussions in this chapter use the term somatization disorder, even in reviewing findings ascertained by these other various criteria.

**Epidemiology**

In the US, somatization disorder is found predominantly in women, with a female/male ratio of approximately 10:1 (see Table 74–1). This ratio is not as large in some other cultures (e.g., in Greeks and Puerto Ricans). Thus, gender- and culture-specific rates are more meaningful than generalized figures. The lifetime prevalence of somatization disorder in US women has been estimated to be between 0.2 and 2%. The magnitude of this discrepancy is attributable, at least in part, to methodological differences. The Epidemiological Catchment Area study (Robins et al. 1984), the most recent large-scale general population study in the US to include an assessment for somatization disorder, found a lifetime risk of somatization disorder of only 0.2–0.3% in US women. However, this study may have underestimated the prevalence of somatization disorder because nonphysician interviewers were used. It is argued that it is difficult for lay interviewers to critically assess whether somatic symptoms are fully explained by physical conditions. As a result, they may more readily accept patients’ general medical explanations of symptoms, resulting in fewer diagnoses of somatization disorder. With age and method of assessment taken into account, the lifetime risk for somatization disorder has been estimated to be 2% in US women (Cloninger et al. 1975).

**Course**

Somatization disorder is rare in children younger than 9 years of age (Robins and O’Neal 1953) (see Table 74–1). Characteristic symptoms of somatization disorder usually begin during adolescence, and the criteria are met by the mid-20s (Guze and Perley 1963). Somatization disorder is a chronic illness characterized by fluctuations in the frequency and diversity of symptoms (Guze et al. 1986). Full remissions occur rarely, if ever. Whereas the most active symptomatic phase is in early adulthood, aging does not appear to lead to total remission (Goodwin and Guze 1989). Pribor et al. (1994) found that women with somatization disorder older than 55 years did not differ from younger somatization patients in the number of somatic symptoms. Longitudinal follow-up studies have confirmed that 80–90% of patients initially diagnosed with somatization disorder will maintain a consistent clinical picture and be re diagnosed similarly after 6–8 years (Cloninger 1993, Cloninger et al. 1986). Women with somatization disorder seen in psychiatric settings are at increased risk for attempted suicide, although such attempts are usually unsuccessful and may reflect manipulative gestures more than intent to die (Martin et al. 1985). It is not clear whether such risk is true for patients with somatization disorder seen only in general medical settings.

**Differential Diagnosis**

As defined in DSM-IV-TR, somatization disorder is characterized by multiple recurring physical symptoms and, as will be described, often multiple psychiatric complaints (Wetzel et al. 1994). Thus, it is not surprising that somatization disorder may present in a manner suggestive of multiple general medical and, although too often forgotten, psychiatric
disorders (Table 74–3). Indeed, it can be said that an essential aspect of somatization disorder is its simulation of other syndromes. As described by Preskorn (1995), “Briquet’s syndrome (i.e., somatization disorder) is fundamentally a syndrome of apparent syndromes” (see Table 74–3). Thus, the first task in the diagnosis of somatization disorder is the exclusion of other suggested medical and psychiatric conditions.

To help in this, Cloninger (1986) identified three features that generally characterize somatization disorder but rarely general medical conditions. Slightly restated, these are (1) involvement of multiple organ systems, (2) early onset and chronic course without development of physical signs or structural abnormalities, and (3) absence of laboratory abnormalities characteristic of the suggested physical disorders (Table 74–4). Another way of characterizing the distinction is the “reverse funnel effect” (Pinta 1995, personal communication). With most general medical conditions, the process of investigation “funnels down” to fewer and fewer specific diagnostic possibilities; in somatization disorder, the more extensive the investigation, the greater the number of suggested disorders.

Several general medical conditions may also fit this pattern and may be confused with somatization disorder. These include multiple sclerosis, other neuropathies, systemic lupus erythematosus, acute intermittent porphyria, other hepatic and hematopoietic porphyrias, hypercalcemia, certain chronic systemic infections such as brucellosis and trypanosomiasis, myopathies, and vasculitides. In general, such conditions begin with disseminated, nonspecific subjective symptoms and transient or equivocal physical signs or laboratory abnormalities.

*All of these symptoms may be reported by patients with somatization disorder, without the clinical consistency and pathological findings to support the diagnosis of neurological, general medical, or psychiatric conditions separate from somatization disorder.

Source: Table originally developed by Ron L. Martin in conjunction with Sheldon H. Preskorn.
Somatization disorder is characterized by excessive psychiatric as well as physical complaints (Wetzel et al. 1994). Thus, other psychiatric disorders, including anxiety and mood disorders and schizophrenia, may be suggested. Although no specific exclusion criteria regarding other psychiatric disorders are given, one must be careful in accepting “comorbidity” and critically evaluate whether suggested syndromes are truly additional syndromes or simply manifestations of somatization disorder (Preskorn 1995).

The overlap between somatization disorder and anxiety disorders may be a particular problem. Patients with somatization disorder frequently complain of many of the same somatic symptoms as patients with anxiety disorders, such as increased muscle tension, features of autonomic hyperactivity, and even discrete panic attacks. Likewise, anxiety disorder patients may report ir rational disease concerns and such somatic complaints as those involving gastrointestinal function that are commonly seen in somatization disorder. However, patients with anxiety disorders neither typically report sexual and menstrual complaints or conversion or dissociative symptoms as in somatization disorder, nor do they have the associated histrionic presentation and personal, marital, and social maladjustment common in patients with somatization disorder (Cloninger 1993).

It must be remembered that an anxiety disorder may be comorbid with somatization disorder. Here, objective observation of the patient rather than reliance on the patient’s report may facilitate an additional diagnosis. For example, patients with somatization disorder may report that they are presently overwhelmed by anxiety while speaking calmly or even cheerfully about their symptoms, or they may be redirectable while in the midst of a reported panic attack.

Mood disorders (in particular depression) frequently present with multiple somatic complaints; especially in certain cultures such as in India, where somatic but not mental complaints are acceptable. A longitudinal history identifying age at onset and course of illness may facilitate discrimination of a mood disorder from somatization disorder. In mood disorders, the age at onset of the somatic symptoms is generally later than in somatization disorder; their first appearance generally correlates discretely with the onset of mood symptoms, and a lengthy pattern of multiple recurring somatic complaints is not seen. Also, resolution of the underlying mood disorder will generally result in disappearance of the somatic complaints.

From the other perspective, patients with somatization disorder often present with depressive complaints. In somatization disorder, a thorough investigation will reveal a multitude of somatic as well as “depressive” symptoms. Interestingly, somatization disorder patients complaining of depression have been found to proffer greater depressive symptoms than individuals with major depression (DeSouza et al. 1988). As in anxiety disorders, major depressive episodes may occur in patients with somatization disorder and must be differentiated from the tendency to have multiple complaints, which is characteristic of somatization disorder. As with anxiety disorders, in considering comorbidity with a depressive disorder, the patient’s reports should be corroborated by collateral information or by direct observation. Thus, the veracity of the self-report of overwhelming depression and suicidal ideation should be doubted if the patient appears cheerful and charming, at least at times, when interviewed, or if the patient is reported to be actively involved in social activities on an inpatient psychiatric service.

Schizophrenia may present with generally single but occasionally multiple unexplained somatic complaints. Interview usually uncovers psychotic symptoms such as delusions, hallucinations, or disorganized thought. In some cases, the underlying psychosis cannot be identified initially, but in time, schizophrenia will become manifest (Goodwin and Guze 1989). Hallucinations are included as examples of conversion symptoms in DSM-IV-TR, as they were in the Purtil, Perley–Guze, and Feighner criteria, which may lead to diagnostic problems (Martin 1996). As discussed in the conversion disorder section, careful analysis of this symptom is warranted so that a misdiagnosis is not made, relegating a patient to long-term neuroleptic treatment on the basis of conversion hallucinations.

Patients with histrionic, borderline, and antisocial personality disorders frequently have an excess of somatic complaints, at times presenting with somatization disorder. Cloninger and Guze (1979) and Cloninger et al. (1975) have identified that antisocial personality disorder and somatization disorder cluster in individuals and within families and may share common causes. Dissociative phenomena, in particular dissociative identity disorder, are commonly associated with somatization disorder (Martin 1996). Because dissociative symptoms are included in the diagnostic criteria for somatization, a separate diagnosis of a dissociative disorder is not made if such symptoms occur only in the course of somatization disorder.

Unlike in hypochondriasis and body dysmorphic disorder, in which preoccupations and fears concerning the interpretation of symptoms predominate, the focus in somatization disorder is on the physical complaints themselves. Unlike in pain disorder and conversion disorder, multiple complaints of different types are reported; by definition in DSM-IV-TR, the history is of pain in at least four sites or functions (e.g., pain with intercourse, pain in swallowing), at least two nonpain gastrointestinal symptoms, at least one nonpain sexual or reproductive symptom, and at least one conversion or dissociative (i.e., pseudoneurological) symptom.

Whereas criteria require the onset of symptoms before the age of 30 years, most patients will have had some symptoms at least by adolescence or early adulthood. Symptoms are often described in a dramatic yet imprecise way and may be reported inconsistently from interview to interview (Martin et al. 1979). The medical history is usually complicated with multiple medical investigations, procedures, and medication trials. If there have been symptoms for at least 6 months but the onset is later than at age 30 years, or if the required number and distribution of symptoms are not evident, undifferentiated somatoform disorder is diagnosed. If the duration has been less than 6 months, somatoform disorder NOS applies. In general, the greater the number and diversity of symptoms, and the longer they have been present without development of signs of an underlying general medical condition, the greater can be the confidence that a diagnosis of somatization disorder is correct.

Etiology and Pathophysiology

Many theories on the cause of somatization disorder have been proposed since the early uterine hypothesis was dismissed. Yet, etiology remains unknown. Psychodynamic hypotheses regarding the physical expression of unconscious conflict by conversion or somatization have been influential. Even Freud assumed a “constitutional diathesis,” as had Charcot before him. Evidence exists for both biological and psychosocial contributions.

Somatization disorder has been shown to be familial. It is observed that in 10–20% of female relatives of patients affected by somatization disorder there is a lifetime risk in US women 10–20 times greater than that in the general population (Guze et al. 1986). Yet, aggregation in families may be attributable to both genetic and environmental factors. A cross-fostering study of a Swedish population demonstrated that genetic background and postnatal influences contribute to the risk of somatization disorder independently (Bohman et al. 1984, Cloninger et al. 1984). Of additional interest are observations that male relatives of patients with somatization disorder show increased rates of antisocial personality and alcoholism, suggesting an etiological link (Cloninger 1993).

Certain promising theories have focused on learning principles with possible organic underpinnings. Ford (1983) and later Quill (1985) postulated a social communication model based on learning theory to explain somatization disorder. Both hypothesized that individuals learn to somatize as a means of expressing their wants and needs and evoking care, nurturance, and support from family and caregivers. That different sex ratios may exist in different cultures suggests that such learning differs from culture to culture.

In the 1970s, impaired information-processing problems involving attention and memory were identified in experimental neuropsychological testing (Ludwig 1972, Bendefeldt et al. 1976). Such deficits may result in vague, nonspecific, and impressionistic description for experience. These may underlie a tendency for excessive somatic complaints and, together with tendencies for impulsiveness and monotony intolerance, may contribute to the often associated multiple personal and social problems (Cloninger 1993). In 1981, Flor-Henry et al. (1981) reported that the pattern of neuropsychological defects found in subjects with somatization disorder differed from that in normal control, schizophrenic, and psychotic depression comparison groups. Subjects with somatization disorder had greater bilateral, symmetrical patterns of frontal lobe dysfunction in comparison with normal control subjects and greater dominant hemisphere impairment than control and depressive subjects. Nondominant hemisphere dysfunction was also identified, with greater impairment in the anterior as opposed to posterior regions. However, subjects with somatization disorder had less nondominant hemisphere disorganization than schizophrenic subjects. Of interest, these findings were similar to findings in male patients with antisocial personality disorder, giving further support to an etiological link with this disorder.

Treatment

First, a “management” rather than a “curative” strategy is recommended for somatization disorder. With the current absence of an identified definitive treatment, a modest, practical, empirical approach should be taken. This should include efforts to minimize distress and functional impairments associated with the multiple somatic complaints, to avoid unwarranted diagnostic and therapeutic procedures and medications, and to prevent potential complications including chronic invalidism and drug dependence.

In such regard, the general recommendations outlined for somatoform disorders should be followed (see Table 74–2). Consistent with these guidelines, Ford (1983) and Quill (1985) recommended that the patient be encouraged to see a single physician with an understanding of and, preferably, experience in treating somatization disorder. This helps limit the number of unnecessary evaluations and treatments. Both Smith et al. (1986) and Murphy (1982) advocated routine, brief, supportive office visits scheduled at regular intervals to provide reassurance and prevent patients from “needing to develop” symptoms to obtain care and attention. This “medical” management can well be provided by a primary care physician, perhaps with consultation with a psychiatrist. The study by Smith et al. (1986) demonstrated that such a regimen led to markedly decreased health care costs, with no apparent decrements in health or satisfaction of patients.

More ambitious goals have been proposed with the recommendation for multiple approaches including individual psychotherapy, nonfocused group therapy, and electroconvulsive therapy (Martin and Yutzy 1994). Whereas early observations indicated some promise with each of these approaches, studies have been generally uncontrolled and used small samples. Subsequent investigations have rarely attempted to replicate reported findings using sophisticated methodology.

Of note in the treatment of somatization disorder was the identification in 1935 by Luff and Garrod (1935) of a three-part approach. Scallet et al. (1976) subsequently endorsed this approach, which they called eclectic, recommending “reeducation, reassurance, and suggestion.” This approach was further developed by multiple authors, such as Quill (1985), Cloninger (1986), Smith et al. (1986), and Murphy (1982), from whom three interrelated components emerge: (1) establishment of a strong physician–patient relationship or bond, (2) education of the patient regarding the nature of the psychiatric condition, and (3) provision of support and reassurance.
The first component, establishing a strong therapeutic bond, is important in the treatment of somatization disorder. Without this, it will be difficult for the patient to overcome skepticism deriving from past experience with many physicians and other therapists who “never seemed to help.” In addition, trust must be strong enough to withstand the stress of withholding unwarranted diagnostic and therapeutic procedures that the patient may feel are indicated. The cornerstone of establishing a therapeutic relationship is laid when the psychiatrist indicates an understanding of the patient’s pain and suffering, legitimizing the symptoms as real. This demonstrates a willingness to provide direct compassionate assistance. A full investigation of the medical and psychosocial histories, including extensive record review, will illustrate to patients the willingness of the psychiatrist to gain the fullest understanding of them and their plight. This also provides another opportunity to evaluate for the presence of an underlying medical condition and to obtain a fuller picture of psychosocial difficulties that may relate temporally to somatic symptoms.

Only after the diagnosis has been clearly established and the therapeutic alliance is firmly in place can the psychiatrist confidently limit diagnostic evaluations and therapies to those performed on the basis of objective findings as opposed to merely subjective complaints. Of course, the psychiatrist should remain aware that patients with somatization disorder are still at risk for development of general medical illnesses so that a vigilant perspective should always be maintained.

The second component is education. This involves advising patients that they suffer from a “medically sanctioned illness,” that is, a condition recognized by the medical community and one about which a good deal is known. Ultimately, it may be possible to introduce the concept of somatization disorder, which can be described in a positive light (i.e., the patient does not have a progressive, deteriorating, or potentially fatal medical condition, and the patient is not “going crazy” but has a condition by which many symptoms will be experienced). A realistic discussion of prognosis and treatment options can then follow.

The third component is reassurance. Patients with somatization disorder often have control and insecurity issues, which often come to the forefront when they perceive that a particular physical complaint is not being adequately addressed. Explicit reassurance should be given that the appropriate inquiries and investigations are being performed and that the possibility of an underlying physical disorder as the explanation for symptoms is being reasonably considered.

In time, it may be appropriate to gradually shift emphasis away from somatic symptoms to consideration of personal and interpersonal issues. In some patients, it may be appropriate to posit a causal theory between somatic symptoms and “stress,” that is, there may be a temporal association between symptoms and personal, interpersonal, and even occupational problems. In patients for whom such “insight” is difficult, behavioral techniques may be useful.

Even following such therapeutic guidelines, patients with somatization disorder are often difficult to treat. Attention-seeking behavior, demands, and manipulation are common, necessitating firm limits and careful attention to boundary issues. This, again, is a management rather than a curative approach. Thus, such behaviors should generally be dealt with directly rather than interpreted to the patient.

During the 1990s cognitive behavior therapy (CBT) began to yield positive preliminary results (Speckens et al. 1995, Lidbeck 1997). Kroenke and Swindle (2000) reported while CBT studies were problematic because of lack of controls, small sample size of imprecise diagnosis (somatization

---

Clinical Vignette 1

A 35-year-old, separated, employed woman was admitted to a psychiatric unit after presenting to the emergency department reporting suicidal feelings that followed a series of arguments with her most recent common-law husband. She reported having been depressed nearly continuously for the past 4 years but had never responded well to antidepressant medications, which often had an “opposite” effect on her. She endorsed virtually all symptoms of a major depressive episode as outlined in DSM-IV-TR. However, she did not appear to be depressed in the interview. In addition to problems with depression, she reported problems with anxiety, complaining of episodes of shortness of breath, chest pain, palpitations, tremulousness, and a feeling of impending doom. At times, she would have prolonged periods with some or all of these symptoms. She reported that she had had a great number of medical problems, but “the doctors keep telling me there’s nothing really wrong with me.” She reported extreme headaches, “like a knife being stuck through the back of my head into my eye,” as well as other headaches virtually every day; other pains including abdominal pain, associated at times with nausea and vomiting; periods of constipation, followed by diarrhea, which had resulted in evaluation for gallbladder and peptic ulcer disease with no significant findings; and pain “in all of my joints,” but particularly in her knees and her back, that she said had been diagnosed as degenerative arthritis at age 27 years, yet no deformities had developed since. She had menstrual problems since menarche, with pain that put her to bed and excessive flow with “big, blue clots,” which resolved only after a hysterectomy 2 years earlier at age 33 years. The mother of four, she reported a long history of sexual problems including pain with intercourse. She had been told that she had a “tipped uterus.” Throughout her life, she was seldom orgasmic and had not enjoyed sex “for years.” She reported episodes of blurred vision with “spots” in front of her eyes, which caused her to stop work. She would also have periods when she just could not hear anything, “like someone put their hands over my ears.” She also reported periods of uncontrollable shaking and a feeling that she was losing control of her body, for which she had been evaluated for seizures. She reported that, at times, she had feared having some serious medical disease, but “with all the workups I have had, I am sure they would have found something by now.” She did relate that she found group therapy with “other people with problems like mine” beneficial.

The patient was diagnosed with somatization disorder and comorbid panic disorder. Panic attacks have ceased since institution of buspirone, but she continues to have multiple somatic complaints. After several months of weekly supportive psychotherapy emphasizing education and reassurance, she is beginning to acknowledge that it is unlikely that physical explanations for her symptoms will be identified. She is also showing progress in dealing more constructively with interpersonal and occupational issues.
disorders vs. “somatization”). There were clear trends toward an increase in physical complaints and medical utilization. Allen et al. (2006) published a randomized clinical study that compared CBT and psychiatric consultation (with the primary care physician) with psychiatric consultation with the primary care physician alone. The CBT plus psychiatric consultation group was found to have a significant greater improvement in symptoms and functioning. However, it remains to be seen whether CBT will gain wide acceptance in the treatment of somatization disorder.

Pharmacological Treatment

No effective somatic treatments for somatization disorder itself have been identified. In the 1960s, Wheatley (1962) reported that low doses of anxiolytic drugs provided symptom amelioration in double-blind clinical trials using general practitioners. He also noted that whereas chlordiazepoxide was recommended for reasons of effectiveness, preference by patients, safety, and symptom relief, the best results were obtained by optimistic physicians using low doses of any anxiolytic medication. Surprisingly little systematic study of the pharmacological management of somatization disorder has been done since.

Patients with somatization disorder may complain of anxiety and depression, suggesting readily treatable comorbid psychiatric disorders. As previously discussed, it is often difficult to distinguish actual comorbid conditions from aspects of somatization disorder itself. Pharmacological interventions are likely to be helpful in the former but not in the latter. At times, such discrimination will be impossible, and an empirical trial of such treatments may be indicated. Patients with somatization disorder are often inconsistent and erratic in their use of medications. They will often report unusual side effects that may not be explained pharmacologically. This makes evaluation of treatment response difficult. In addition, drug dependence and suicide gestures and attempts are not uncommon.

**UNDIFFERENTIATED SOMATOFORM DISORDER**

**Definition and Diagnostic Features**

As defined in DSM-IV-TR, this category includes disturbances of at least 6 months’ duration, with one or more unintentional, clinically significant, medically unexplained physical complaints. In a sense, it is a residual category, subsuming syndromes with somatic complaints that do not meet criteria for any of the “differentiated” somatoform disorders yet are not better accounted for by any other mental disorder. On the other hand, it is a less residual category than somatoform disorder NOS, in that the disturbance must last at least 6 months (see Figure 74–1). Virtually any unintentional, medically unexplained physical symptoms causing clinically significant distress or impairment can be considered. In effect, this category serves to capture syndromes that resemble somatization disorder but do not meet full criteria.

The term undifferentiated somatoform disorder was introduced in 1987 with DSM-III-R, replacing the atypical somatoform disorder of DSM-III. However, the category has not been well used, not only by psychiatrists but also by primary care physicians for whom identification of such a syndrome could be useful. Terms that have been used in a similar manner include subsyndromal, forme fruste, or abridged somatization disorder (Kirmayer and Robbins 1991). Escobar et al. (1989), defining an abridged syndrome as requiring at least six significant unexplained somatic symptoms for women and four for men, argued that especially in primary care settings, such a condition was much more common than a full somatization disorder and it predicted disability and future use of medical services. This group also argued that this construct met many of the suggested requirements for validity as a psychiatric disorder, although adequate follow-up and family studies have not yet been done.

Due to this as well as the underuse of such a construct, perhaps attributable, at least in part, to the ambiguity of designation as undifferentiated, consideration was given to differentiating an abridged somatization syndrome as “multisomatiform disorder” in DSM-IV-TR. However, owing to uncertainties about the nature of such an entity, especially as to overlap with other syndromes such as anxiety and depressive disorders, and because the few data available suggested a variable course (Cloninger 1996), unlike somatization disorder, such a syndrome was left under the undifferentiated somatoform disorder rubric in DSM-IV-TR. A more specific designation could have proved misleading clinically, promoting a false sense of security, with a tendency to preclude...
efforts to uncover a general medical or substance-related explanation for symptoms or to identify another psychiatric condition better accounting for the symptoms.

The DSM-IV-TR undifferentiated somatoform disorder category is little changed from DSM-III-R. Exclusion occurs on the basis of symptoms not better accounted for by another mental disorder rather than by occurrence exclusively during the course of another mental disorder.

**Epidemiology**

Some have argued that undifferentiated somatoform disorder is the most common somatoform disorder. Escobar et al. (1991), using an abridged somatization disorder construct requiring six somatic symptoms for women and four for men, reported that 11% of non-Hispanic US whites and Hispanics, 15% of US blacks, and 20% of Puerto Ricans in Puerto Rico fulfilled criteria. A preponderance of women was evident in all groups except the Puerto Rican sample (see Table 74–1). According to Escobar, such an abridged somatoform syndrome is 100 times more prevalent than a full somatization disorder.

**Course**

As shown in it, appears that the course and prognosis of undifferentiated somatoform disorder are highly variable. This is not surprising, because the definition of this disorder allows a great deal of heterogeneity.

**Differential Diagnosis**

In comparison to when the full criteria for the well-validated somatization disorder are met, exclusion of an as-yet undiscovered general medical or substance-induced explanation for physical symptoms is far less certain when the less stringent criteria for undifferentiated somatoform disorder are met. Thus, the diagnosis of undifferentiated somatoform disorder should remain tentative, and new symptoms should be carefully investigated.

Because undifferentiated somatoform disorder represents somewhat of a residual category, the major diagnostic process, once occult general medical conditions and substance-induced explanations have been considered, is one of exclusion. As shown in Figure 74–1, whether the somatic symptoms are intentionally produced as in malingering and factitious disorder must be addressed. Here, motivation for external rewards (for malingering) and a pervasive intent to assume the sick role (for factitious disorder) must be assessed. The next consideration is whether the somatic symptoms are the manifestation of another psychiatric disorder. Anxiety and mood disorders commonly present with somatic symptoms; high rates of anxiety and major depressive disorders are reported in patients with somatic complaints attending family medicine clinics (Kirmayer et al. 1993). Of course, undifferentiated somatoform disorder could be diagnosed in addition to one of these disorders, so long as the symptoms are not accounted for by the other psychiatric disorder. Crucial in this determination is whether the symptoms are present during periods in which the anxiety or mood disorders are not actively present.

Next, other somatoform disorders must be considered. In general, undifferentiated somatoform disorders are characterized by unexplained somatic complaints; the most common according to Escobar et al. (1989) are female reproductive symptoms, excessive gas, abdominal pain, chest pain, joint pain, palpitations, and fainting, rather than preoccupations or fears as in hypochondriasis or body dysmorphic disorder. However, a patient with some manifestations of these two disorders but not meeting full criteria could conceivably receive a diagnosis of undifferentiated somatoform disorder. An example is a patient with recurrent yet shifting hypochondriacal concerns that do respond to medical reassurance. If symptoms are restricted to those affecting the domains of sexual dysfunction, pain, or pseudoneurological symptoms, and the specific criteria for a sexual dysfunction, pain disorder, and/or conversion disorder are met, the specific disorder or disorders should be diagnosed. If other types of symptoms or symptoms of more than one of these disorders have been present for at least 6 months, yet criteria for somatization disorder are not met, undifferentiated somatoform disorder should be diagnosed. By definition, undifferentiated somatoform disorder requires a duration of 6 months. If this criterion is not met, a diagnosis of somatization disorder NOS should be considered.

Patients with an apparent undifferentiated somatoform disorder should be carefully evaluated for somatization disorder. Typically, patients with somatization disorder are inconsistent historians, at one evaluation reporting a large number of symptoms fulfilling criteria for the full syndrome, at another time endorsing fewer symptoms (Martin et al. 1979). In addition, with follow-up, additional symptoms may become evident, and criteria for somatization disorder will be satisfied. Patients with multiple somatic complaints not diagnosed with somatization disorder because of a reported onset later than 30 years of age may be inaccurately reporting a later age at onset. If the late age at onset is accurate, the patient should be carefully scrutinized for an occult general medical condition.

In addition to the range of symptoms specified in the other somatoform disorders, patients complaining primarily of fatigue (chronic fatigue syndrome), bowel problems (irritable bowel syndrome), or multiple muscle aches/weakness (fibromyalgia) can be considered for undifferentiated somatoform disorder. Substantial controversy exists regarding the etiology of such syndromes. Even if an explanation on the basis of a known pathophysiological mechanism cannot be established, many argue that the syndromes should be considered general medical conditions. However, for the time being, these syndromes could be considered in a highly tentative manner under the undifferentiated somatoform disorder rubric. Careful reconsideration of the psychiatric label should be undertaken at regular intervals if the symptoms persist. The psychiatrist should remain ever vigilant to the emergence of another general medical or psychiatric condition. Noteworthy is also the fact, when patients are diagnosed with chronic fatigue syndrome, careful evaluation procedures as recommended by an international study group should be followed (Fukuda et al. 1994).

**Etiology and Pathophysiology**

Theories of etiology involving the concept of somatization have been posited by some. As reviewed by Kirmayer and Robbins (1991), somatization can be viewed as “a pattern of illness behavior by which bodily idioms of distress may serve as symbolic means of social regulation as well as protest.
or contestation.” However, as previously discussed, such hypotheses have defied verification.

Clinical Vignette 2

A 34-year-old woman was referred for psychiatric evaluation of “possible depression and anxiety” by her primary care physician. For at least the past 2 years, she complained of painful, prolonged menstruation with excessive flow, abdominal cramping even when not menstruating, fatigue, and headaches. Medical investigation including extensive blood work, gynecological examination, and gastrointestinal evaluations did not establish any objective findings. Despite her reports of excessive menstruation, she had never been anemic and had not lost any weight. Her headaches varied. Some were preceded by an aura and were associated with nausea, vomiting, and photophobia, but most were consistent with “tension headaches” and relieved by acetaminophen. When discussing her personal life, the patient became tearful. Although she remained married, she reported little support from her husband of 9 years who was dedicated to his work, spending excessive hours at the office and on the road, leaving the patient with much of the responsibility for the household and their three young children aged 8, 6, and 3 years. She felt that she could not tolerate the situation much longer. She was sad but thought that if her home situation improved, she would have hope. She felt exhausted from the time she awoke in the morning to when she went to bed, had some loss of appetite but no weight loss, remained interested in things, but “just didn’t have the time.” She reported trouble concentrating but attributed it to being interrupted every 5 minutes with some “kid problem.” She felt down on herself and that she was “wasting all the potential I have” taking care of the home and her children. She denied any suicidal ideation but believed that “if I died everyone would see how much I do around here!” She denied feeling tense or anxious or any episodes of apprehension.

She had no prior history of psychiatric problems, and before the onset of her menstrual and abdominal problems, she had been in good health. However, on further exploration, she reported that she had a period in her teens when she had similar problems after breaking up with a boyfriend and experiencing some academic problems. She also later reported occasional miscellaneous medical problems for which she sought medical attention; these were generally associated with “something that was going around.”

The psychiatric impression was (1) possible undifferentiated somatoform disorder but rule out depressive disorder NOS or dysthymic disorder; (2) rule out somatization disorder; although the patient’s history as presently obtained did not fulfill criteria, it was noted that she was an inconsistent historian, and thus a thorough review of her medical records was indicated; (3) possible unidentified general medical condition; and (4) partner relational problem. Recommendations included that (1) the patient’s home situation be assessed for possible redistribution of the work and responsibility load; (2) the patient and her husband be referred for marital counseling; (3) while the patient’s psychiatric history was being further assessed, an antidepressant medication with a low sedation side effect profile should be started on a trial basis; and (4) the primary care physician should be advised to be vigilant for a possible unidentified underlying general medical condition, given the ambiguity of the patient’s psychiatric status.

If it is assumed that undifferentiated somatoform disorder is simply an abridged form of somatization disorder, etiological theories reviewed under that diagnosis should apply. An intriguing research question is why the syndrome is fully expressed in some and only partially expressed in others.

Treatment

In view of the broad inclusion and minimal exclusion criteria for undifferentiated somatoform disorder, it is difficult to make treatment recommendations beyond the generic guidelines outlined for the somatoform disorders in general. More definitive recommendations await a more extensive empirical database. A substantial proportion of patients with undifferentiated somatoform disorders improve or recover with no formal therapy. However, appropriate psychotherapy and pharmacological intervention may accelerate the process.

Kellner (1991) outlined some recommendations for patients with symptoms of headache, fibromyalgia, and chronic fatigue syndrome, conditions that some would include under undifferentiated somatoform disorder. Generally recommended are brief psychotherapy of a supportive and educative nature. As with somatization disorder, the physician–patient relationship is of great importance. Judicious use of pharmacotherapy may also be of benefit; particularly if the somatoform syndrome is intertwined with an anxiety or depressive syndrome. Here, usual antianxiety and antidepressant medications are recommended. Patients with unexplained pains may benefit from pain management strategies as outlined in the pain disorder section.

CONVERSION DISORDER

Definition and Diagnostic Features

As defined in DSM-IV-TR, conversion disorders are characterized by symptoms or deficits affecting voluntary motor or sensory function that suggest yet are not fully explained by a neurological or other general medical condition or the direct effects of a substance. The diagnosis is not made if the presentation is explained as a culturally sanctioned behavior or experience, such as bizarre behaviors resembling a seizure during a religious ceremony. Symptoms are not intentionally produced or feigned, that is, the person does not consciously contrive a symptom for external rewards, as in malingering, or for the intrapsychic rewards of assuming the sick role, as in factitious disorder.

Four subtypes with specific examples of symptoms are defined: with motor symptom or deficit (e.g., impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia, and urinary retention); with sensory symptom or deficit (e.g., loss of touch or pain sensation, double vision, blindness, deafness, and hallucinations); with seizures or convulsions; and with mixed presentation (i.e., has symptoms of more than one of the other subtypes). The list of examples is also contained among the pseudoneurological symptoms listed in the diagnostic criteria for somatization disorder. Although determination is highly subjective and of questionable reliability and validity, association with psychological factors is required.

To a great extent, the concept of a conversion disorder derived from the work of neurologists such as Charcot,
Conversion Disorder

A. One or more symptoms or deficits affecting voluntary motor or sensory function that suggest a neurological or other general medical condition.

B. Psychological factors are judged to be associated with the symptom or deficit because the initiation or exacerbation of the symptom or deficit is preceded by conflicts or other stressors.

C. The symptom or deficit is not intentionally produced or feigned (as in factitious disorder or malingering).

D. The symptom or deficit cannot, after appropriate investigation, be fully explained by a general medical condition, or by the direct effects of a substance, or as a culturally sanctioned behavior or experience.

E. The symptom or deficit causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or warrants medical evaluation.

F. The symptom or deficit is not limited to pain or sexual dysfunction, does not occur exclusively during the course of somatization disorder, and is not better accounted for by another mental disorder.

Specify type of symptom or deficit:

With motor symptom or deficit (e.g., impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia, and urinary retention)

With sensory symptom or deficit (e.g., loss of touch or pain sensation, double vision, blindness, deafness, and hallucinations)

With seizures or convulsions (includes seizures or convulsions with voluntary sensory components)

With mixed presentation (if symptoms of more than one category are evident)

Hallucinations are included among the sensory nervous symptoms in DSM-IV-TR. Whereas the concept of conversion hallucinations has a long tradition (Martin 1996), DSM-III and DSM-III-R noted hallucinations as a manifestation of only two nonpsychotic disorders: posttraumatic stress disorder, in which a traumatic event is reexperienced, and multiple personality disorder (dissociative identity disorder in DSM-IV-TR), wherein one or more personalities hear the voice of, talk with, or engage in activities with one or more of the other personalities. Inclusion of hallucinations as a conversion symptom was supported by the somatization disorder field trial, in which one-third of a large sample of nonpsychotic women with evidence of unexplained somatic complaints reported a history of hallucinations. Among the 40% who had symptoms that met criteria for somatization disorder.
disorder, more than half reported hallucinations (Martin 1995, unpublished data). Women with other conversion symptoms were more likely to report hallucinations than were those with no other conversion symptoms.

In general, conversion hallucinations (referred to by some as pseudohallucinations) differ in several ways from those in psychotic conditions. Conversion hallucinations typically occur in the absence of other psychotic symptoms, insight that the hallucinations are not real may be retained, and they often involve more than one sensory modality, whereas hallucinations in psychoses generally involve a single sensory modality, usually auditory. Conversion hallucinations also often have a naive, fantastic, or childish content, as if they are part of a fairy tale, and are described eagerly, sometimes even provocatively, as an interesting story (e.g., “I was driving downtown and a flying saucer flew over my car and I saw you [the psychiatrist] in a window and I heard your voice calling to me”). They often bear some understandable psychological purpose, although the patient may not be aware of intent. In the example given, the “sighting” was reported at the time that no further sessions were scheduled.

Epidemiology

Vastly different estimates of the incidence and prevalence of conversion disorder have been reported. Much of this difference may be attributable to methodological differences from study to study, including the changing definition of conversion disorder, ascertainment procedures, and populations studied. General population estimates have generally been derived indirectly, extrapolating from clinic or hospital samples.

Conversion symptoms themselves may be common; it was reported that 25% of normal postpartum and medically ill women had a history of conversion symptoms at some time during their life (Cloninger 1993), yet in some instances, there may have been no resulting clinically significant distress or impairment. Lifetime prevalence rates of treated conversion symptoms in general populations are much more modest, ranging from 11 to 500 per 100,000 (Martin 1996) (see Table 74–1). About 5–24% of psychiatric outpatients, 5–14% of general hospital patients, and 1–3% of outpatient psychiatric referrals reported a history of conversion symptoms (Cloninger 1993, Ford and Folks 1985, Toone 1990), although their current treatment was not necessarily for conversion symptoms. A rate of nearly 4% of outpatient neurological referrals (Perkin 1989) and 1% of neurological admissions (Ziegler and Paul 1954) involved conversion disorder. In virtually all studies, an excess (to the extent of 2:1 to 10:1) of women reported conversion symptoms relative to men (Ljunberg 1957, Stefansson et al. 1976, Raskin et al. 1966). In part, this may relate to the simple fact that women seek medical evaluation more often than men do, but it is unlikely that this fully accounts for the sex difference. There is a predilection for lower socioeconomic status; less educated, less psychologically sophisticated, and rural populations are overrepresented (Veith 1965, Weinstein et al. 1969, Lazare 1981, Folks et al. 1984). Consistent with this, higher rates (nearly 10%) of outpatient psychiatric referrals are for conversion symptoms in “developing” countries (Stafanis et al. 1976). As countries develop, there may be a declining incidence in time, which may relate to increasing levels of education, and medical and psychological sophistication (Nandi et al. 1992).

Course

Age at onset is typically from late childhood to early adulthood. Onset is rare before the age of 10 years (Maloney 1980) and after 35 years, but cases with an onset as late as the ninth decade have been reported (Weddington 1979). The likelihood of a neurological or other medical condition is increased when the age at onset is in middle or late life. Development is generally acute, but symptoms may develop gradually as well. The course of individual conversion symptoms is generally short; half (Folks et al. 1984) to nearly all (Carter 1949) symptoms remit by the time of hospital discharge. However, symptoms relapse within 1 year in one-fifth to one-fourth of patients. Typically, one symptom is present in a single episode, but multiple symptoms are generally involved longitudinally. Factors associated with good prognosis include acute onset, clearly identifiable precipitants, a short interval between onset and institution of treatment, and good intelligence (Toone 1990). Conversion blindness, aphonia, and paralysis are associated with relatively good prognosis, whereas patients with seizures and tremor do more poorly. Some patients diagnosed initially with conversion disorder will have a presentation that meets criteria for somatization disorder when they are observed longitudinally (Kent et al. 1995).

Individual conversion symptoms are generally self-limited and do not lead to physical changes or disabilities. Rarely, physical sequelae such as atrophy may occur. Marital and occupational problems are not as frequent in patients with conversion disorder as they are in those with somatization disorder (Tomasson et al. 1991, Coryell and House 1984). In a long-term follow-up study, excess mortality by unnatural causes was observed (Coryell and House 1984). However, the reason for this was unclear in that none of the deaths was by suicide.

Differential Diagnosis

As shown in Figure 74–1, the first consideration is whether the conversion symptoms are explained on the basis of a general medical condition. Because conversion symptoms by definition affect voluntary motor or sensory function (thus pseudoneurological), neurological conditions are usually suggested, but other general medical conditions may be implicated as well. Neurologists are generally first consulted by primary care physicians for conversion symptoms; psychiatrists become involved only after neurological or general medical conditions have been reasonably excluded. Nonetheless, psychiatrists should have a good appreciation of the process of making such exclusions. More than 13% of actual neurological cases are diagnosed as functional before the elucidation of a neurological illness (Perkin 1989). Even after referred, vigilance for an emerging general medical condition should continue. A significant percentage—21% (Gatfield and Guze 1962) to 50% (Slater and Glithero 1965)—of patients diagnosed with conversion symptoms are found to have neurological illness on follow-up.

Apparent conversion symptoms mandate a thorough evaluation for possible underlying physical explanation. This evaluation must include a thorough medical history, physical
(especially neurological) examination, and radiographical, blood, urine, and other tests as clinically indicated. Reliance should not be placed on determination of whether psychological factors explain the symptom. As reviewed by Cloninger (1987), such determinations are unreliable except, perhaps, in the cases in which there is a clear and immediate temporal relationship between a psychosocial stressor and the symptom, or in the cases in which similar situations led to conversion symptoms in the past. A history of previous conversion or other unexplained symptoms, particularly if somatization disorder is diagnosable, lessens the probability that an occult medical condition will be identified (Cloninger 1993). Although conversion symptoms may occur at any age, symptoms are most often first manifested in late adolescence or early adulthood. Conversion symptoms first occurring in middle age or later should increase suspicion of an occult physical illness.

Symptoms of many neurological illnesses may appear inconsistent with known neurophysiological or neuropathological processes, suggesting conversion and posing diagnostic problems. These illnesses include multiple sclerosis, in which blindness due to optic neuritis may initially present with normal fundi; myasthenia gravis, periodic paralysis, myoglobinuric myopathy, polymyositis, and other acquired myopathies, in which marked weakness in the presence of normal deep tendon reflexes may occur; and Guillain–Barré syndrome, in which early extremity weakness may be inconsistent (Cloninger 1993).

Complicating diagnosis is the fact that physical illness and conversion or other apparent psychiatric overlay are not mutually exclusive. Patients with physical illnesses that are incapacitating and frightening may appear to be exaggerating symptoms. Also, patients with actual neurological illness will also have “pseudo” symptoms. For example, patients with actual seizures may have pseudoseizures as well (Desai et al. 1982). Considering these observations, psychiatrists should avoid a rash and hasty diagnosis of conversion disorder when faced with symptoms that are difficult to interpret.

As with the other somatoform disorders, symptoms of conversion disorder are not intentionally produced, in distinction to malingering or factitious disorder. To a large part, this determination is based on assessment of the motivation for external rewards (as in malingering) or for the assumption of the sick role (as in factitious disorder). The setting is often an important consideration. For example, conversion-like symptoms are frequent in military or forensic settings, in which obvious potential rewards make malingering a serious consideration.

A diagnosis of conversion disorder should not be made if a conversion symptom is fully accounted for by a mood disorder or by schizophrenia (e.g., disordered motility as part of a catatonic syndrome of a psychotic mood disorder or schizophrenia). If the symptom is a hallucination, it must be remembered that the descriptors differentiating conversion from psychotic hallucinations should be seen only as rules of thumb. Differentiation should be based on a comprehensive assessment of the illness. In the case of hallucinations, posttraumatic stress disorder and dissociative identity disorder (multiple personality disorder) must also be excluded. If the conversion symptom cannot be fully accounted for by the other psychiatric illness, conversion disorder should be diagnosed in addition to the other disorder if it meets criteria (e.g., an episode of unexplained blindness in a patient with a major depressive episode). In hypochondriasis, neurological illness may be feared (“I have strange feelings in my head; it must be a brain tumor”), but the focus here is on preoccupation with fear of having the illness rather than on the symptom itself as in conversion disorder.

By definition, if symptoms are limited to sexual dysfunction or pain, conversion disorder is not diagnosed. Criteria for somatization disorder require multiple symptoms in multiple organ systems and functions, including symptoms affecting motor or sensory function (conversion symptoms) or memory or identity (dissociative symptoms). Thus, it would be superfluous to make an additional diagnosis of conversion disorder in the context of a somatization disorder.

A last consideration is whether the symptom is a culturally sanctioned behavior or experience. Conversion disorder should not be diagnosed if symptoms are clearly sanctioned or even expected, are appropriate to the sociocultural context, and are not associated with distress or impairment. Seizure-like episodes, such as those that occur in conjunction with certain religious ceremonies, and culturally expected responses, such as women “swooning” in response to excitement in Victorian times, qualify as examples of these symptoms.

Etiology and Pathophysiology

The term conversion implies etiology because it is derived from a hypothesized mechanism of converting psychological conflicts into somatic symptoms, often symbolically (e.g., repressed rage is converted into paralysis of an arm that could be used to strike). A number of psychological factors have been promoted as part of such an etiological process, but evidence for their essential involvement is scanty at best. Theoretically, anxiety is reduced by keeping an internal conflict or need out of awareness by symbolic expression of an unconscious wish as a conversion symptom (primary gain). However, individuals with active conversion symptoms often continue to show marked anxiety, especially on psychological tests (Lader and Sartorious 1968, Mears and Horvath 1972). Symbolism is infrequently evident, and its evaluation involves highly inferential and unreliable judgments (Raskin et al. 1966). Overinterpretation of symbolism in persons with occult medical condition may contribute to misdiagnosis. Secondary gain, whereby conversion symptoms allow avoidance of noxious activities or the procurement of otherwise unavailable support, may also occur in persons with medical conditions, who may take advantage of such benefits (Raskin et al. 1966, Watson and Buranen 1979).

Individuals with conversion disorder may show a lack of concern out of keeping with the nature or implications of the symptom (the so-called la belle indifférence). However, indifference to symptoms is not invariably present in conversion disorder (Lewis and Berman 1965) and is also seen in individuals with general medical conditions (Weinstein et al. 1969), on the basis of denial or stoicism (Pincus 1982). Conversion symptoms may present in a dramatic or histrionic fashion and may be highly suggestive. A dramatic presentation is also seen in distressed individuals with medical
conditions. Even symptoms based on an underlying medical condition will respond to suggestion, at least temporarily (Gatfield and Guze 1962). In many instances, preexisting personality disorders (in particular histrionic personality disorder) are evident and may predispose to conversion disorder. Persons with conversion disorder may often have a history of confused sexuality (Lewis 1974) many (one-third) report a history of sexual abuse, especially incestuous. Thus, two-thirds may not report such a history. Individuals with conversion disorder are often reported to be the youngest or the youngest of a sex in sibling order, but this is not a consistent finding (Ziegler et al. 1960, Stephens and Kamp 1962).

If not directly etiological, many psychosocial factors have been suggested as predisposing to conversion disorder. At a minimum, many persons with conversion disorder are in chaotic domestic and occupational situations. As previously mentioned, individuals from rural backgrounds and those who are psychologically and medically unsophisticated appear to be predisposed, as are those with existing neurological disorders. In the last case, a tendency to conversion symptoms has been attributed to “modeling,” that is, patients with neurological disorders are likely to have observed in others, as well as in themselves, various neurological symptoms, which they then may simulate as conversion symptoms.

Available data suggest a genetic contribution. Conversion symptoms are more frequent in relatives of individuals with conversion disorder (Toone 1990). In a nonblinded study, rates of conversion disorder were found to be elevated tenfold in female (fivefold in male) relatives of patients with conversion disorder (Ljunberg 1957). Accumulated data from available twin studies show 9 concordant and 33 discordant monozygotic pairs and no concordant but 43 discordant dizygotic pairs (Inouye 1972). Nongenetic familial factors, particularly incestuous childhood sexual abuse, may also be involved in some. Nearly one-third of individuals with medically unexplained seizures reported childhood sexual abuse, compared with less than 10% of those with complex partial epilepsy (Alper et al. 1993). Data looking specifically at abuse history in other well-defined conversion disorder cases are not available.

**Treatment**

Reports of the treatment of conversion disorder date from those of Charcot, which generally involved symptom removal by suggestion or hypnosis. Breuer and Freud, using such psychoanalytic techniques as free association and abreaction, by which repressed material, particularly regarding relationships being suggested. This is in contrast to attempts at abreaction, by which repressed material, particularly regarding a painful experience or a conflict, is brought back to consciousness.

If symptoms do not resolve with such conservative approaches, a number of other techniques for symptom resolution may be instituted. It does appear that prompt resolution of conversion symptoms is important because the duration of conversion symptoms is associated with a greater risk of recurrence and chronic disability (Cloninger 1993). The other techniques include narcoanalysis (e.g., amobarbital interview), hypnosis, and behavioral therapy (Ford 1995). Narcoanalysis, amobarbital or another sedative-hypnotic medication such as lorazepam is given intravenously to the point of drowsiness. Sometimes this is followed by administration of a stimulant medication, such as methamphetamine. The patient is then encouraged to discuss stressors and conflicts. This technique may be effective acutely, leading to at least temporary symptom relief as well as expansion of the information known about the patient. This technique has not been shown to be especially effective with more chronic conversion symptoms. In hypnotherapy, symptoms may be removed with the suggestion that the symptoms will gradually improve posthypnotically. Information regarding stressors and conflicts may be explored as well. Formal behavioral therapy, including relaxation training and even aversive therapy, has been proposed and reported by some to be effective. In addition, simply manipulating the environment to interrupt reinforcement of the conversion symptom is recommended.

Anecdotally, somatic treatments including phenothiazines, lithium, and electroconvulsive therapy have been reported effective. However, in many cases, this may be attributable to simple suggestion. In other cases, resolution of another psychiatric disorder, such as a psychotic disorder or a mood disorder, may have led to the symptom’s removal. It should be evident from the preceding discussion that in acute conversion disorders, it may be not the particular technique but the influence of suggestion that is specifically associated with symptom relief. It is likely that in various rituals, such as exorcism and other religious ceremonies, immediate “cures” are based on suggestion. Suggestion seems to play a major role in the resolution of “mass hysteria,” in which a group of individuals who believe that they have been exposed to some noxious influence such as a “toxin” or even a “spell” experience similar symptoms that do not appear to have any organic basis. Often, the epidemic can be contained if affected individuals are segregated. Simple announcements that no such factor has been identified and that symptoms experienced by the group have been linked to mass hysteria have been effective.

Thus far, this discussion has centered on acute treatment primarily for symptom removal. Longer term
approaches include strategies previously discussed for somatization disorder—a pragmatic, conservative approach involving support and exploration of various conflict areas, particularly of interpersonal relationships. A certain degree of insight may be attained, at least in terms of appreciating relationships between various conflicts and stressors and the development of symptoms. Others advocate long-term, intensive, insight-oriented dynamic psychotherapy.

Clinical Vignette 3

A 47-year-old woman was referred for psychiatric consultation by her primary care physician at the recommendation of a neurologist. She had been admitted to the hospital 2 days earlier, after presenting with mild acidosis attributed to poor control of her insulin-dependent diabetes mellitus. She had become concerned that insulin was “making me fat” and had been taking it erratically for several weeks. On admission, she also complained of generalized muscle weakness, more pronounced on the left side, especially in the arm, and reported that she had had a “stroke” affecting the right side 1 year before, for which she was not hospitalized. On examination, the neurologist observed that the patient showed no atrophy or spasticity and that deep tendon reflexes were decreased but equal bilaterally. On testing of the left upper extremity, the patient was observed to show weakness in extending and flexing the arm against resistance, yet more careful examination revealed residual strength inconsistent with that shown in these tests. Her primary care physician reported some question of a stroke 1 year before, which was never clearly ascertained. A “hysterical component to the neurological symptoms” was considered. Nonetheless, diagnostic procedures were instituted, including magnetic resonance imaging. No abnormalities were seen by this test. Two days later, it was concluded that a stroke was improbable, and noting reports of depressed mood, the neurologist recommended psychiatric consultation.

When seen by the psychiatric consultant, she still complained of the weakness, although it was somewhat improved and not so clearly localized to the left side. She also mentioned that she had been depressed for several weeks before admission and that she had been treated with some success with fluoxetine in the past. She reported multiple conflicts concerning her living situation. She was living with her married son and felt that his wife resented her presence. She felt “trapped” in that she could not afford to live independently. Medical records indicated that diabetes mellitus had been diagnosed at age 36 years and was treated with oral hypoglycemic agents until age 41 years, when insulin became necessary for adequate control. The record also revealed several episodes of transient unexplained weakness as well as occasional problems with headaches and joint pain going back to age 26 years, with several mentions of temporal proximity of such symptoms to marital and occupational difficulties. Yet, criteria for somatization disorder were not fulfilled.

The psychiatrist’s provisional diagnoses were (1) psychological factors affecting medical condition (noncompliance with insulin regimen); (2) conversion disorder, with motor symptom or deficit; and (3) possible major depressive disorder, recurrent. Treatment with sertraline, 50 mg at bedtime, was recommended. It was also suggested to the patient that her tests were now completed and that it was expected that her weakness would continue to improve. When the psychiatrist visited her the next day, she reported that her weakness was better and that she was also beginning to feel less depressed. The patient was encouraged to continue to see her primary care physician and to comply with his recommendations, and she was referred to social work for assistance with her living situation. Referral for outpatient psychiatric care was also recommended.

This clinical vignette illustrates several important aspects concerning the diagnosis, course, and treatment of conversion disorder. As is not uncommon, the patient does suffer from a medical illness to which many symptoms can ordinarily be attributed. However, the extent of her complaints, the lack of neuroanatomical verification, and inconsistencies of her report and the documented history suggested a possibility that her motor symptoms were not fully attributable to a general medical condition. This interpretation was supported by her past history of apparent conversion symptoms as well as some other somatic complaints. Although she was also complaining of depression, her history was vague, and her “response” to 1 day of treatment with an antidepressant drug was unlikely to be pharmacological. Her motor symptoms were resolving with reassurance and suggestion, such that the short-term prognosis for her motor symptoms was good. However, her history of noncompliance with medical treatment, and multiple situational and interpersonal problems indicated the advisability of continued psychosocial if not psychiatric intervention.

PAIN DISORDER

Definition and Diagnostic Features

The term “pain disorder” was new to DSM-IV-TR. It replaced the DSM-III-R designation somatoform pain disorder. Because the disorder was already included in the somatoform grouping, somatoform was redundant. In addition, whereas the DSM-III-R somatoform pain disorder was more neutral than the DSM-III psychogenic pain disorder, it maintained differentiation between imaginary or exaggerated and real pain, following a dualistic dichotomy of separating mind and body. The matter of determining psychogenicity was always a problem (Williams and Spitzer 1982). As reviewed by Cloninger (1993), raters show only moderate agreement on such questions even when they are given the same information. Yet, both DSM-III psychogenic pain disorder and DSM-III-R somatoform pain disorder required that the pain not have an organic or pathophysiological explanation and that the complaint or impairment be greatly in excess of what would be expected from the physical findings.

As defined in DSM-IV-TR, the essential feature of pain disorder is pain with which psychological factors “have an important role in the onset, severity, exacerbation, or maintenance”. Pain disorder is subtyped as pain disorder associated with psychological factors and pain disorder associated with both psychological factors and a general medical condition. The third possibility, pain disorder associated with a general medical condition, is not considered to be a mental disorder, because the requirement is not met that psychological factors play an important role. Thus, the DSM-IV-TR concept of pain disorder as a mental disorder
was broadened and allowed the psychiatrist much greater specificity in considering etiological factors and a more useful schema for differential diagnosis. The focus is placed on the presence of psychological factors rather than the exasperating determination of whether the pain is attributable to organic disease.

In addition, DSM-IV-TR requires that pain be the predominant focus of the clinical presentation and that it cause clinically significant distress or impairment. Specifiers of acute (duration of less than 6 months) and chronic (duration of 6 months or longer) are provided. Both DSM-III and DSM-III-R required chronicity: prolonged in DSM-III, for at least 6 months in DSM-III-R. This left no place for clinically significant syndromes of recent onset or limited duration and undoubtedly contributed to the fact that DSM-III and DSM-III-R pain diagnoses were little used.

With the changes outlined, the DSM-IV-TR-defined pain disorder is compatible with current theories of pain and should be more clinically applicable.

### Epidemiology

Given the tortuous course of changing diagnostic criteria, only estimates can be made for the epidemiological parameters of pain disorder. As to pain itself, some empirical studies suggest that it is common. Perhaps an indirect evidence of this is the proliferation of pain clinics nationally. Of course, many patients attending these clinics fall into the category of pain disorder associated with a general medical condition, but undoubtedly, some also have involvement of psychological factors as required for a diagnosis of pain disorder as a mental disorder. The same would apply to the 10–15% of adults in the US in any given year who have work disability because of back pain (Osterweis et al. 1987). Pain has been found to be a predominant symptom in 75% of consecutive general medical patients, with 75% of these (thus 50% overall) judged as having no identifiable physical cause (King 1994). As reviewed by Stoudemire (1988), no apparent physical basis is found in 40–50% of patients presenting with nonspecific abdominal pain. At least half of such patients show major personality problems in addition,
with such aberrations associated with poor outcome. Whereas primary care and other nonpsychiatric physicians probably see most pain patients, 38% of psychiatric inpatient admissions (Delaplaine et al. 1978) and 18% attending a psychiatric outpatient clinic (Chaturvedi 1987) report pain as a significant problem.

**Course**

Given the heterogeneity of conditions subsumed under the pain disorder rubric, course, and prognosis vary widely. The subtyping at 6 months is of significance. The prognosis for total remission is good for pain disorders of less than 6 months' duration. However, for syndromes of greater than 6 months’ duration, chronicity is common. The site of the pain may be another factor. As described by Stoudemire and Sandhu (1987), certain anatomically differentiated pain syndromes can be distinguished, and each has its own characteristic pattern. These include syndromes characterized primarily by headache, facial pain, chest pain, abdominal pain, and pelvic pain. In such syndromes, symptoms tend to be recurrent, with relapses occurring in association with stress. A high rate of depression has been observed among patients with unexplained facial pain. Facial pain is often alleviated by antidepressant medication. This effect has been observed in both patients with depressive symptoms and those without.

Other factors affecting course and prognosis include associated psychiatric illness and external reinforcement. Employment at the outset of treatment predicts improvement (Martin 1995). Chronicity is more likely in the presence of certain personality diagnoses or traits, such as pronounced passivity and dependency. External reinforcement includes litigation involving potential financial compensation or disability. Continuation of the pain disorder may prove more lucrative than its resolution and return to work. Level of activity, which is generally associated with improvement, is discouraged by fears of losing compensation. Thus, although outright malingering may be rare (Leavitt and Sweet 1986), pain behaviors are often reinforced and maintained. Habituation with addictive drugs is associated with greater chronicity.

**Differential Diagnosis**

As shown in Figure 74–1, the diagnostic approach begins with assessment of whether the presentation is fully explained by a general medical condition. If not, it may be assumed that psychological factors play a major role. If it is judged that psychological factors do not play a major role, a diagnosis of pain disorder associated with a general medical condition may apply. As previously mentioned, this does not have a mental disorder code.

If psychological factors are involved, the first consideration is whether the pain is feigned. If so, either malingering or factitious disorder is diagnosed, depending on whether external incentives or assumption of the sick role is the motivation. Evidence of malingering includes consideration of external rewards relative to the chronology of the development and maintenance of the pain. In factitious disorder, a pattern of successive hospitalizations and medical evaluations is evident. Inconsistency in presentation, lack of correspondence to known anatomical pathways or disease patterns, and lack of associated sensory or motor function changes suggest malingering or factitious disorder, but pain disorder associated with psychological factors may show this pattern as well. The key question is whether the patient is experiencing rather than feigning the pain.

Determination of the relative contributions of psychological and general medical factors is difficult. Of course, careful assessment of the nature and severity of the potential underlying medical condition and the nature and degree of pain that would be expected should be made. Traditionally, the so-called conversion V or neurotic triad (consisting of elevation of the hypochondriasis and hysteria scales with a lower score on the depression scale) on the Minnesota Multiphasic Personality Inventory has been purported to indicate emotional indifference to the somatic concerns as might be expected if the symptom is attributable to psychological factors rather than organic disease. However, evidence indicates that this configuration may also occur as an adjustment to chronic illness.

A diagnosis of pain disorder requires that the pain be of sufficient severity to warrant clinical attention, that is, it causes clinically significant distress or impairment. A number of instruments have been developed to assess the degree of distress associated with the pain. Such measures include the numerical rating scale and visual analog scale as described by Scott and Huskisson (1976), the McGill Pain Questionnaire, and the West Haven-Yale Multidimensional Pain Inventory (Osterweis et al. 1987).

**DSM-IV-TR includes** a number of exclusionary conventions. By definition, if pain is restricted to pain with sexual intercourse, the sexual disorder, dyspareunia, not pain disorder, is diagnosed. If pain occurs in the context of a mood, anxiety, or psychotic disorder, pain disorder is diagnosed only if it is an independent focus of clinical attention and is not better accounted for by the other disorder, a highly subjective judgment.

If pain occurs exclusively during the course of somatization disorder, pain disorder is not diagnosed because pain symptoms are part of the criteria for somatization disorder and are thereby subsumed under the more comprehensive diagnosis. Because somatization disorder is a lifelong condition, this exclusion generally applies in someone with somatization disorder by history. Important here is that in addition to pain, somatization disorder involves multiple symptoms of the gastrointestinal system, the reproductive system, and the central and peripheral nervous systems; whereas in pain disorder, the focus is on pain symptoms only.

Specification of acute versus chronic pain disorder on the basis of whether the duration is less than or greater than 6 months is an important distinction. Whereas acute pain, in most cases, will be linked with physical disorders, when pain remains unexplained after 6 months, psychological factors are often involved (Cloninger 1993). However, the psychiatrist must remember that a significant minority (in one study 19%) of patients with chronic pain of no apparent physical origin will ultimately be found to have occult organic disease (Cloninger 1993).

In patients with unexplained pelvic pain, psychiatrists should be warned about cavalier conclusions regarding the absence of physical disease. With laparoscopy, a high frequency of occult organic disease has been identified in several studies. Thus, laparoscopy may be indicated in patients with pelvic pain. Electromyography may be helpful
Etiology and Pathophysiology

In considering the etiology of pain disorder, possible mechanisms of pain itself must be considered. As reviewed by King (1994), the definition of pain sanctioned by the International Association for the Study of Pain Subcommittee on Taxonomy is “an unpleasant sensory and emotional experience associated with actual or potential tissue damage.” It goes on to acknowledge that pain is not simply “activity induced in the nociceptor and nociceptive pathways by a noxious stimulus” but “is always a psychological state.” Thus, it accepts the hypothesis that pain involves psychological as well as physical factors.

Many theories of the etiology and pathophysiology of pain involving both biological and psychological factors have been proposed. It is known that a neuromatrix descends from the cerebral cortex and medulla, which inhibits the firing of pain transmission neurons when it is activated (Cloninger 1993). This system is apparently mediated by the endogenous opiate-like compounds, endorphins, and by serotonin. Indeed, metabolites of both of these neurotransmitters may be reduced in the cerebrospinal fluid of chronic pain patients (von Knorring and Attkisson 1979).

The gate control theory developed by Melzack and Wall (1983), as reviewed by King (1994), links biological and psychological factors. It hypothesizes a gate-like mechanism involving the dorsal horn of the spinal cord by which large A-beta fibers as well as small A-delta and C fibers carry impulses from the periphery to the substantia gelatinosa and T-cells in the spinal cord. Activation of the large fibers inhibits whereas activation of the small fibers facilitates transmission to the T-cells. In addition, impulses descending from the brain, influenced by cognitive processes, may either inhibit or facilitate transmission of pain impulses. Such a mechanism may explain how psychological processes affect pain perception.

By definition, both pain disorder associated with psychological factors and pain disorder associated with both psychological factors and a general medical condition involve psychological factors. In the case of the former, it is presumed that there is little contribution from general medical conditions; in the latter, both physical and psychological factors contribute. A plethora of not necessarily mutually exclusive theories has been proposed to explain how this takes place.

As reviewed by Cloninger (1993), psychological constructs involving learning theories, both operant and classical conditioning, may apply. In operant paradigms, pain-related complaints are reinforced by increased attention, relief from obligations, monetary compensation, and the pleasurable effects of analgesics. In classical conditioning, originally neutral settings such as a workplace or bedroom where pain was experienced come to evoke pain-related behavior. Social and cultural attitudes may also have effects. Patients with unexplained pain are more likely than others to have close relatives with chronic pain. Although findings have differed from study to study, ethnic differences may also have effects, such as greater pain tolerance in Irish and Anglo-Saxon groups in comparison to southern Mediterranean groups.

Treatment

Psychosocial and Somatic Treatments

Treatment of pain overall has been well summarized by King (1994). An overriding guideline is that the psychiatrist not do anything that will actually perpetuate and even promote “pain-related behavior.” Thus, a major goal is to encourage activity. Other guidelines include avoidance of sedative–antianxiety drugs, judicious use of analgesics on a fixed interval schedule so as not to reinforce pain-related behaviors, avoidance of opioids, and consideration of alternative treatment approaches such as relaxation therapy. Depression should be treated with appropriate antidepressant drugs, not sedative–antianxiety medications. The difficulties in managing pain disorder patients have resulted in the establishment of many clinics and programs especially designed for pain. Referral to such a service may be indicated. Intervention should best be provided early in the course of the syndrome, before pain-related behaviors become entrenched. Once continuing disability compensation is established, therapeutic efforts become much more difficult.

The preceding general guidelines apply whether or not a general medical basis for the pain is involved. Of course, if only pain disorder associated with psychological factors is involved, psychological management will be the mainstay. For patients with pain associated with general medical factors (not a mental disorder) in which psychological factors do not play a major role, efforts should be made to prevent the development of psychological problems in response to the resulting distress, isolation and loss of function, and iatrogenic effects such as exposure to potentially addicting drugs.

In acute pain, the major goal is to relieve the pain (Osterweis et al. 1987). Thus, pharmacological agents generally play a more significant role than in chronic syndromes. Whereas the risk of developing opioid dependence appears to be surprisingly low (4 per 12,000) among patients without a prior history of dependence (Porter and Jick 1980), nonopioid agents should be used whenever they can be expected to be effective. As discussed for chronic pain, these include particularly acetaminophen and the nonsteroidal antiinflammatory drugs (NSAIDs), of which aspirin is considered a member. Even if an opioid analgesic is employed, these drugs should be continued as adjuncts; often, they lessen the required dose of the opioid.

It is with the chronic syndromes that proper management is crucial to ease distress and prevent the development of additional problems. As advised by King (1994), the overriding goal is to maintain function, because total relief of the pain may not be possible. Physical and occupational therapy may play a major role. There may be resistance to the involvement of a psychiatrist as an indication that the pain is not seen as real. Such issues must first be resolved. An attempt should be made to ascertain the roles that psychological and general medical factors play in the maintenance of the pain.

A large variety of psychotherapies including individual, group, and family strategies have been employed.
Two techniques that warrant special attention are operant conditioning and CBT. In operant conditioning, the pattern of reinforcement of pain behavior by medication, attention, and excuse from responsibilities is to be interrupted and reinforcement shifted to usual daily activities. To assess the role of operant conditioning, it may be necessary to have patients keep a diary and to interview family members to identify any conditioning patterns. In CBTs, the goal is the identification and correction of attitudes, beliefs, and expectations. Biofeedback and relaxation techniques may be used to minimize muscle tension that may aggravate if not cause pain. Hypnosis may also be used to achieve muscle relaxation and to help the patient “dissociate” from the pain.

Pharmacological intervention may also be useful in chronic syndromes. Effort should be made to avoid opioids if possible. Agents to be tried first include antidepressants, acetaminophen, NSAIDs (including aspirin), and anticonvulsants such as carbamazepine. Antidepressants seem particularly useful for neuropathic pain, headache, facial pain, fibrositis, and arthritis (including rheumatoid arthritis). Analgesic action seems to be independent of antidepressant effects. Most work has been done with the tricyclic antidepressants; other classes, such as the monoamine oxidase inhibitors (MAOIs) and the selective serotonin reuptake inhibitors (SSRIs), may be effective as well. Although it was thought that the action is mediated by serotonergic effects, agents such as desipramine with predominately noradrenergic activity seem to be effective as well. NSAIDs, of which aspirin, ibuprofen, naproxen, and piroxicam are commonly used examples, may alleviate pain through inhibition of prostaglandin synthesis. Unfortunately, this effect may also contribute to side effects, such as aggravation of peptic or duodenal ulcers and interference with renal function. For patients unable to tolerate NSAIDs, acetaminophen should be tried.

If opioid analgesics are used, it is recommended that use be tied to objectives such as increasing level of activity rather than simply pain alleviation (King 1994). Milder opioids, such as codeine, oxycodone, and hydrocodone, should be implemented first. The once widely used propoxyphene has less analgesic effect than these drugs; it is not devoid of abuse potential as once thought and is not recommended. Pure opioid agonists such as morphine, methadone, and hydromorphone should be tried next. Meperidine, also in this class, is no longer recommended for chronic pain because prolonged use allows accumulation of a toxic metabolite, normeperidine, a cerebral irritant, which may cause anxiety, psychosis, or seizures. Meperidine may also have a lethal interaction with MAOIs.

There are no advantages to mixed opioid agonist–antagonists. The once commonly used pentazocine should be avoided because it has abuse potential and psychotomimetic effects in some patients. It remains to be seen whether newer agents (buprenorphine, butorphanol, and nalbuphine) have lower abuse potential as claimed. Above all, psychiatrists should be judicious in the use of opioid analgesics, considering not only their abuse potential but their large number of side effects including constipation, nausea and vomiting, excessive sedation, and, in higher doses, respiratory depression that may be fatal (King 1994).

In addition to pharmacotherapy, a number of other “physical” techniques have been used, such as acupuncture and transcutaneous electrical nerve stimulation. These carry little risk of adverse effects or aggravation of the pain disorder. Other procedures such as trigger point injections, nerve blocks, and surgical ablation may be recommended if specifically indicated by an underlying general medical condition.

As can be seen in the preceding discussion, the management of pain disorders is not monomodal. A great number of psychological and physical factors and interventions may be considered.

### Clinical Vignette 4

A 60-year-old dentist was referred to a psychiatrist for an evaluation by an insurance company from which the patient was receiving $2,000 per month on the basis of disability resulting from “groin” pain. The pain began suddenly nearly 5 years before while he was working at his office. He described it as a burning pain most severe in his left scrotum and perianal area and radiating down his left leg. The pain was not aggravated by urination, defecation, sexual intercourse, or activity. Thus began a series of diagnostic and treatment procedures including a radical prostatectomy with vascular sparing, a partial colonectomy, a lumbar laminectomy, and intrathecal anesthetic injection of vertebral facets. Whereas objective indications for each surgery were present, including chronic prostatitis and seminal vesiculitis, diverticulitis and hemorrhagic dysplasia of the colon, and probable compression of a lumbar vertebra, none of these procedures appreciably relieved his pain. A working diagnosis of lumbosacralplexopathy was given by the neurologist who had assumed his care. The patient was receiving oxycodone (5 mg) and acetaminophen (325 mg) (Percocet) three to four times daily, naproxen (Naprosyn) (250 mg three times daily), and carbamazepine (Tegretol) (100 mg/day). The patient took medications religiously and never took more than prescribed. He reported that with this regimen, “the edge was taken off the pain,” but he did not have adequate relief. Yet, when attempts were made to discontinue the Percocet, “it became intolerable.” After the onset of the pain, the patient was not able to maintain his practice, leaving it in the hands of his son who was also a dentist; “Even if I could stand the pain, I couldn’t concentrate on my work well enough to do justice to my patients.”

He worked only occasionally, performing some simple procedures. “I wish I could return to work because I certainly can’t support myself on my disability check. Besides, I’m like an adult hyperactive child. I need to stay busy.”

At the time of the onset of the pain, the patient was in the midst of highly contested divorce settlement proceedings. The divorce from his wife of 12 years had resulted from the wife’s long-standing infidelity, which had come as a total surprise to the patient when he discovered it. He previously divorced a wife of 26 years after she had become unfaithful. The patient had a successful dental practice. Throughout his life, he had been a hard worker, a workaholic, supporting himself through dental school; subsequently, he put his children through college and graduate or professional school. He had no history of alcohol or drug abuse. He had an episode of depression and “bizarre behavior” at the time of his first divorce, was hospitalized and treated with medications, but did not follow through with recommended outpatient care. With the current episode of pain, he also had a depressive syndrome, initially with ideas that other family members had...
been involved in a conspiracy with his wife and that he himself was being investigated by the Central Intelligence Agency. He was again briefly hospitalized and treated with haloperidol and fluoxetine; he was prescribed fluoxetine and lithium on discharge. For follow-up care, he chose an old professional friend as his psychiatrist, who maintained him with fluoxetine (20 mg/day) and saw the patient sporadically for supportive psychotherapy, which according to the patient “didn’t amount to much.” Lithium had been discontinued on the insistence of the patient, who reported that it made him “dopey.” The patient now minimized the episode leading to hospitalization, saying that he was “upset and hurt” by his wife’s infidelity. He reported that he still felt depressed but was much better. “Who wouldn’t be depressed if they were in pain all the time and couldn’t work?”

Psychiatric diagnoses included (1) pain disorder associated with psychological and general medical features, and (2) major depressive disorder, recurrent, with psychotic features in the past. It was also concluded that the patient was disabled from performing the duties of his occupation. Recommendations included (1) that the patient be considered temporarily disabled and be given compensation, (2) referral to a regional pain clinic for more thorough evaluation of pain management, and (3) referral to a psychiatrist (preferably incorporated in the pain clinic referral) with whom the patient does not have a friendship such that objectivity could be maintained.

This clinical vignette illustrates a number of factors important in consideration of pain disorders. First, in this case, it is virtually impossible to disect the pain complaint as either wholly physically or psychologically based. In all likelihood, the two are intertwined here. Malingering is unlikely. The patient, at least consciously, is motivated to return to work because of both interest and financial incentive. The level of disability compensation is not adequate to maintain his customary style of living. It does not appear that the patient is simply drug seeking, because he has no history of substance abuse and has never overused his opioid medication. Second, the patient fits one stereotype of a person vulnerable to a pain disorder, considering his strong work ethic and reluctance to see things on a psychological or emotional level. Third, despite many evaluations, it does not appear that the patient is yet receiving optimal pain management. He is continued on an opioid analgesic. Whereas treatment with an NSAID and carbamazepine may be appropriate, the carbamazepine is dosed such that it is unlikely to be at a therapeutic plasma level, and a tricyclic antidepressant, which would be the treatment of choice, has not been tried. Last, the psychiatrist is faced with the dilemma of either recommending disability compensation, which may work to reinforce the pain behavior and prolong it, or not recommending compensation to which the patient is legitimately entitled.

**HYPOCHONDRIASIS**

**Definition and Diagnostic Features**

As defined in DSM-IV-TR, the essential feature in hypochondriasis is preoccupation with fears or the idea of having a serious disease based on the “misinterpretation of bodily symptoms.” This is in contrast to somatization disorder, conversion disorder, and pain disorder, in which the symptoms themselves are the predominant focus. There was some debate in the development of DSM-IV-TR as to whether it was necessary that a body complaint be present. On the basis of empirical data, however, it was determined that this requirement was a valid one and helped to distinguish the “disease conviction” of hypochondriasis from “disease fear” as in phobic disorder (Cote et al. 1996). Bodily symptoms may be interpreted broadly to include misinterpretation of normal body functions. In hypochondriasis, the preoccupation persists despite reassurance from physicians and the accumulation of evidence to the contrary. As in the other somatoform disorders, symptoms must result in clinically significant distress or impairment in important areas of functioning. The duration must be at least 6 months.

Hypochondriasis is not diagnosed if the hypochondriacal concerns are better accounted for by another psychiatric disorder, such as major depressive episodes or various psychotic disorders with somatic delusions.

Clinical descriptions of a syndrome characterized by preoccupation with body function are found in the writings of the Hippocratic era (Stoudemire 1988). The Greeks attributed the syndrome to disturbances of visceræ below the xiphoid cartilage (i.e., hypochondria). Even into the 19th century, hypochondriasis was applied specifically to...
somatoform complaints below the diaphragm, rather than the
topographically nonspecific concept of more recent usage
(Komier 1993). As reviewed by Murphy (1990), Gillespie
in 1928 encapsulated a concept of hypochondriasis consist-
ent with the current concept, emphasizing preoccupation
with a disease conviction “far in excess of what is justified,”
which showed “an indifference to the opinion of the environ-
ment, including irresponsiveness to persuasion.” Gillespie
considered hypochondriasis a discrete disease entity. DSM-
I did not include hypochondriasis as a separate illness.
Hypochondriacal preoccupation was mentioned as one of
the malignant symptoms observed in psychotic but not reac-
tive depression. DSM-II included hypochondriacal neuropsy-
chiatric populations, because patients with hypochon-
driasis are convinced that they suffer from some physical
illness. To date, study of such populations suggests that
4–9% of patients in general medical settings suffer from
hypochondriasis (Fallon et al. 1993).

Of note, similar subsequent studies by Gureje et al.
(1997), Escobar et al. (1998), and Noyes et al. (2000) all
reported frequencies in the same general range (2.2–10.6).

It does appear that hypochondriasis is equally common
in males and females. Data concerning socioeconomic class
are conflicting.

Course
Data are conflicting, but it appears that the most common
age at onset is in early adulthood. Available data suggest
that approximately 25% of patients with a diagnosis of
hypochondriasis do poorly. 65% show a chronic but fluc-
tuating course, and 10% recover. This pertains to the full
syndrome. A much more variable course is seen in patients
with just some hypochondriacal concerns. It appears that
acute onset, absence of a personality disorder, and absence
of secondary gain are favorable prognostically.

Differential Diagnosis
As shown in Figure 74–1, the first step in approaching
patients with distressing or impairing preoccupation with or
fears of having a serious disease is to exclude the possibility
of explanation on the basis of a general medical condition.
Fears that may seem excessive may also occur in patients
with general medical conditions with vague and subjective
symptoms early in their disease course. These include neu-
rological diseases, such as myasthenia gravis and multiple
sclerosis, endocrine diseases, systemic diseases that affect several
organ systems, such as systemic lupus erythematosus, and
occult malignant neoplasms (Kellner 1991). The disease con-
viction of hypochondriasis may actually be less amenable to
medical reassurance than the fears of patients, with general
medical illnesses, who may at least temporally accept such
encouragement. Hypochondriacal complaints are not often
intentionally produced such that differentiation from malin-
gering and factitious disorder is seldom a problem.

Exclusion is made if the preoccupation is better
accounted for by another psychiatric disorder. DSM-IV-TR
lists generalized anxiety disorder, obsessive–compulsive dis-
order, panic disorder, a major depressive episode, separation
anxiety, or another somatoform disorder as candidates.
Chronology will be of utmost importance in such discrimi-
nations. Hypochondriacal concerns occurring exclusively
during episodes of another disturbance, such as an anxiety
or depressive disorder, do not warrant an additional diag-
nosis of hypochondriasis. The presence of other psychiatric
symptoms will also be helpful. For example, a patient with
hypochondriacal complaints as part of a major depressive
episode will show other symptoms of depression, such as
sleep and appetite disturbance, feelings of worthlessness,
and self-reproach, although depressed elderly patients may

Epidemiology

Some degree of preoccupation with disease is apparently
common. As reviewed by Kellner (1991), 10–20% of
“normal” and 45% of “neurotic” persons have intermittent
unfounded worries about illness, with 9% of patients doub-
ting reassurances given by physicians. In another review,
Kellner (1985) estimated that 50% of all patients attending
physicians’ offices “suffer either primary hypochondriacal
symptoms or have minor somatic disorders with hypochon-
driacal overlay.” How these relate to hypochondriasis as
a disorder is difficult to assess because these estimates do
not appear to distinguish between a focus on the symptoms
themselves (as in somatization disorder) and preoccupation
with the implications of the symptoms (as in hypochondri-
sis). The Epidemiological Catchment Area study (Robins
et al. 1984) did not assess for hypochondriasis. A 1965 study
reported prevalence figures ranging from 3 to 13% in dif-
ferent cultures (Kenyon 1965), but it is not clear whether
this represents a syndrome comparable to the current defi-
nition or just hypochondriacal symptoms. As already noted,
many patients manifest some hypochondriacal symptoms
as part of other psychiatric disorders, and others have tran-
sient hypochondriacal symptoms in response to stresses
such as serious physical illness yet never fulfill the inclusion
criteria for DSM-IV-TR hypochondriasis. Assessment of
the incidence and prevalence of hypochondriasis undoubt-
edly requires study of general or primary care rather than
psychiatric populations, because patients with hypochon-
driasis are convinced that they suffer from some physical
illness. To date, study of such populations suggests that
4–9% of patients in general medical settings suffer from
hypochondriasis (Fallon et al. 1993).
deny sadness or other expressions of depressed mood. A con-
found factor is that patients with hypochondriasis often have coexisting anxiety or depressive syndromes (Kenyon
1965). Again, characterizing the symptoms by chronology
will be useful. Treatment trials may also have diagnostic sig-
nificance. Depressed patients who are hypochondriacal may
respond to non-SSRI antidepressant medications or electro-
convulsive therapy (often necessary to reverse a depressive
state of sufficient severity to lead to such profound symp-
toms), with resolution of the hypochondriacal as well as the
depressive symptoms.

Hypochondriasis is differentiated from other somato-
form disorders such as pain, conversion, and somatization
disorders by its predominant feature of preoccupation with
and fears of having an underlying illness based on the mis-
interpretation of body symptoms, rather than the physical
symptoms themselves. Patients with these other somatoform
disorders at times are concerned with the possibility of
underlying illness, but this will generally be overshadowed
by a focus on the symptoms themselves.

The next consideration is whether the belief is of delu-
sional proportions. Patients with hypochondriasis, although
preoccupied, generally acknowledge the possibility that
their concerns are unfounded. Delusional patients do not.
Somatic delusions of serious illness are seen in some cases of
schizophrenia and in delusional disorder, somatic type.
In general, patients with schizophrenia who have such delu-
sions also show other signs of schizophrenia, such as disor-
ganized speech, peculiarities of thought and behavior, hal-
lucinations, and other delusions. Belief that an underlying
illness is being caused by some bizarre process may also be
seen (e.g., “I’m trying not to defecate because it will cause
my brain to turn to jelly”). Patients with schizophrenia
may also show improvement with neuroleptic treatment, at
least in the “active” symptoms of their illness, under which
somatic delusions are included.

Differentiation from delusional disorder, somatic
type, may be more difficult. It is often a thin line between
preoccupation and fear that is a conviction and that which
is a delusion. Often, the distinction is made on the basis of
whether the patient can consider the possibility that the
conviction is erroneous. Yet, patients with hypochondriasis vary
in the extent to which they can do this. DSM-IV-TR acknowled-
ges this by its inclusion of the specifier with poor insight.
In the past, some argued that differentiation could be made
on the basis of response to neuroleptics, especially pimozide;
patients with delusional disorder, but not hypochondriasis,
respond. Interestingly, there is now at least one case report
of successful treatment of a syndrome corresponding to
delusional disorder, somatic type, in a nondepressed patient
with the SSRI paroxetine (Brophy 1994). As with hypochon-
driasis, response was obtained only when the dose was raised
beyond an antidepressant dose (to 60 mg/day).

If it is concluded that the preoccupations are not
delusional, the next consideration is whether the duration
requirement of 6 months has been met (see Figure 74–1).
Syndromes of less than 6 months’ duration are diagnosed
under either somatoform disorder NOS or adjustment
disorder if the symptoms are an abnormal response to a
stressful life event. The reason to make such a distinc-
tion is to distinguish hypochondriasis from transient syn-
dromes, the longitudinal course of which has been shown
to be more variable, suggesting heterogeneity (Barsky et al.
1993).

Other diagnostic considerations include whether the
preoccupations or fears are restricted to preoccupations with
being overweight, as in anorexia nervosa, with the inappropri-
ateness of one’s sex characteristics, as in a gender identity
disorder, or with defects in appearance, as in body dysmorphic
disorder. The preoccupations of hypochondriasis resemble
the obsessions, and the health checking and efforts to obtain
reassurance resemble the compulsions of obsessive–compul-
sive disorder. However, if such manifestations are health
centered only, obsessive–compulsive disorder is not diag-
nosed. If, on the other hand, nonhealth-related obsessions
and compulsions are present, obsessive–compulsive disorder
may be diagnosed in addition to hypochondriasis.

Etiology and Pathophysiology

Until recently, psychoanalytic theories of etiology
predominated. Freud hypothesized that hypochondriasis
represented “the return of object libido onto the ego with
cathexis of the body” (Viederman 1985). Subsequently, the
cathexis to body hypothesis was elaborated on to include
interpretations involving disturbed object relations—
displacement of repressed hostility to the body to com-
municate anger indirectly to others. Dynamic mechanisms
involving masochism, guilt, conflicted dependency needs,
and a need to suffer and be loved at the same time have
also been suggested (Stoudemire 1988). The presence of
such “narcissistic” mechanisms has been suggested as the
reason that patients with hypochondriasis were “unanalyz-
able.” Other psychological theories involve defense against
feelings of low self-esteem and inadequacy, perceptual and
cognitive abnormalities, and operant conditioning involving
reinforcement for assumption of the sick role.

Biological theories have been suggested as well. Hypo-
chondriacal ideas have been attributed to a hypervigilance
to insult, including overperception of physical problems
(Barsky and Klerman 1983). This has been posited in particular in reference to hypochondriasis as an aspect of
depression or anxiety disorders. Hypochondriasis has been
included by some in the posited obsessive–compulsive spec-
trum disorders along with obsessive–compulsive and body
dysmorphic disorders, anorexia nervosa, Tourette’s disorder,
trichotillomania, pathological gambling, and other impul-
sive disorders (Hollander 1993). All these disorders involve
repetitive thoughts or behaviors that patients are unable to
delay or inhibit without great difficulty. Evidence for this
clustering includes observations of clinical improvement
with SSRIs such as fluoxetine even in nondepressed patients
with hypochondriasis, body dysmorphic disorder, obses-
sive–compulsive disorder, and anorexia nervosa. Because
such a response is not evident with non-SSRI antidepress-
sants, some type of common serotonin dysregulation is sug-
gested for these disorders.

Treatment

Psychosocial and Somatic Treatments

Until recently, it appeared that patients with hypochondriasis
as a primary condition benefited, but only modestly, from
psychiatric intervention. Patients referred early for psy-
chiatric evaluation and treatment showed a slightly better
prognosis than those continuing with only medical evaluations and treatments (Kellner 1983). Of course, the first step in treatment is getting the patient to a psychiatrist. Patients with hypochondriasis generally present initially to nonpsychiatric physicians and are often reluctant to see a psychiatrist. Referral should be done sensitively, with the referring physician stressing to the patient that his or her distress is real and that psychiatric evaluation will be a supplement to, not a replacement for, continued medical care.

Initially, the generic psychotherapeutic techniques outlined for the somatoform disorders in general should be followed. As reviewed by Fallon et al. (1993), dynamic psychotherapy is of minimal effectiveness, supportive–educative psychotherapy as described by Kellner (1991) is only somewhat helpful, and primarily for those with syndromes of less than 3 years’ duration, and CBT, especially response prevention of checking rituals and reassurance seeking, was seen only as moderately effective at best. Interestingly, more recent studies by Warwick et al. (1996), Clark et al. (1990), and Barsky and Ahern (2004) have all strongly suggested that the specific procedures of CBT including psychoeducation, cognition restructuring, and exposure-response prevention are all active components in improving hypochondriacal symptoms (e.g., reducing anxiety, health concerns, functional impairment). These studies and others lead Taylor et al. (2005) to conclude that there is now clear evidence that hypochondriasis can be effectively managed using CBT. Time will tell whether CBT will gain wide acceptance.

Pharmacotherapy of comorbid depressive or anxiety syndromes was often effective, and control of such syndromes aided in general management, yet hypochondriasis itself was not ameliorated. Although controlled trials are lacking, anecdotal and open-label studies suggest that serotoninergic agents such as clomipramine and the SSRI fluoxetine may be effective in ameliorating hypochondriasis. Similar effects have been reported with the other SSRIs. Response to fluoxetine has been reported with doses recommended for obsessive–compulsive disorder, rather than usual antidepressant doses (i.e., 60–80 mg/day rather than 20–40 mg/day). Several problems with medications have been reported including relapse at discontinuation (Viswanathan and Paradis 1991), worsening of symptomology because of side effects (Fallon 2001) and significant placebo effect (Fallon et al. 1996). It is also noteworthy that there have been scattered case reports over the years describing a reduction in hypochondriacal symptoms as a result of antipsychotics including pimozide and the newer atypicals including olanzapine. Pharmacotherapy is best combined with the generic psychotherapy recommendations for somatoform disorders, as well as with cognitive–behavioral techniques to disrupt the counterproductive checking and reassurance-seeking behaviors.

Clinical Vignette 5

A 26-year-old single man presented for psychiatric evaluation at the insistence of his job supervisor, who was concerned that the patient was not keeping up with his assignments at work. The patient reported that he could not concentrate on his work because for the past 4 years he had been constantly preoccupied with the thought that there was something seriously wrong with his arms resulting from a “strain” while he moved furniture. Although there was minimal pain associated, he was convinced that the problem would progress and he would lose the use of his arms. Multiple consultations with orthopedic surgeons and neurologists had not identified any underlying physical problem. He rejected physical therapy for fear that it would only aggravate the underlying problem. Physical activity involving his arms was avoided as much as possible. Not able to avoid driving to work, he wore a prosthesis that he had constructed from various elastic bandages “to prevent any strain.” He arrived at work early to be ensured a parking space that was easy to enter.

In addition to this preoccupation, he also feared that ulcerative colitis was developing. This began after his father died of a gastrointestinal hemorrhage when the patient was 16 years old. Initially diagnosed as possible ulcerative colitis, it was found at postmortem examination to be due to a ruptured abdominal aneurysm. The patient fully accepted this diagnosis, yet he could not stop thinking that he was at risk for ulcerative colitis despite multiple gastrointestinal evaluations that failed to find any signs of the illness in him. He adhered to a strict diet, avoiding any “roughage,” and was concerned about “regularity.” He would awaken every day 2 hours earlier than necessary to have enough time for a bowel movement before going to work. The slightest gastrointestinal sensation would aggravate his concern, and he would carefully examine his stool for any signs of blood or mucus. He reported that his work attendance was excellent but that most of the time he would just sit at his desk and move papers around to look busy while thinking about his health problems. “I have a civil service job and until now I got away with it.” The patient had no prior psychiatric evaluations. For both of his health concerns, he was able to consider the possibility that there was no underlying physical cause, “but I can’t stop thinking about them. What if all the doctors are wrong?”

The psychiatrist’s diagnosis was hypochondriasis, with poor insight. The patient was to be further evaluated for a concurrent major depressive episode and also for nonhealth preoccupations that would suggest an additional diagnosis of obsessive–compulsive disorder. The psychiatrist’s recommendations included (1) a trial of fluoxetine to be increased to 60 mg/day if tolerated, (2) supportive–educative psychotherapy to ensure compliance and for support, and (3) cognitive–behavioral therapy to reinforce use of his arms, to extinguish assumptions that he needed a special diet, and to reassure him that dire consequences would not occur if his bowel movements were not absolutely punctual.

This clinical vignette illustrates several important typical aspects of hypochondriasis. First, the onset of the disorder was early, in the late teens, with consolidation of symptoms by early adulthood. Second, a chronic course was observed, with some fluctuation in severity. The physical complaints themselves were minimal. It was the preoccupation with fears of underlying illness that predominated and led to distress and impairment.

BODY DYSMORPHIC DISORDER

Definition and Diagnostic Features

As defined in DSM-IV-TR, the essential feature of this disorder is preoccupation with an imagined defect in appearance or a markedly excessive concern with a minor anomaly.
Body Dysmorphic Disorder

A. Preoccupation with an imagined defect in appearance. If a slight physical anomaly is present, the person’s concern is markedly excessive.

B. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The preoccupation is not better accounted for by another mental disorder (e.g., dissatisfaction with body shape and size in anorexia nervosa).

Epidemiology

Knowledge of such parameters is still incomplete. In general, patients with body dysmorphic disorder first present to nonpsychiatrists such as plastic surgeons, dermatologists, and internists because of the nature of their complaints and are not seen psychiatrically until they are referred (de Leon et al. 1989). Many resist or refuse referral because they do not see their problem as psychiatric; thus, study of psychiatric clinic populations may underestimate the prevalence of the disorder. It has been estimated that 2% of patients seeking corrective cosmetic surgery suffer from this disorder (Andreasen and Bardach 1977). General population studies have identified rates of occurrence from 0.7 to 2.3% (Faravelli et al. 1997, Otto et al. 2001, Mayville et al. 1999).
Course
Age at onset appears to peak in adolescence or early adulthood (Phillips 1991). Body dysmorphic disorder is generally a chronic condition, with a waxing and waning of intensity but rarely full remission (Phillips et al. 1993). In a lifetime, multiple preoccupations are typical; in one study, the average was four (Phillips et al. 1993). In some, the same preoccupation remains unchanged. In others, new perceived defects are added to the original ones. In others still, symptoms remit, only to be replaced by others. The disorder is often highly incapacitating, with many patients showing marked impairment in social and occupational activities. Perhaps a third becomes housebound. Most attribute their limitations to embarrassment concerning their perceived defect, but the attention and time-consuming nature of the preoccupations and attempts to investigate and rectify defects also contribute. The extent to which patients with body dysmorphic disorder receive surgery or medical treatments is unknown. Superimposed depressive episodes are common, as are suicidal ideation and suicide attempts. Actual suicide risk is unknown.

In view of the nature of the defects with which patients are preoccupied, it is not surprising that they are found most commonly among patients seeking cosmetic surgery. Preoccupations persist despite reassurance that there is no defect to surgically correct. Surgery or other corrective procedures rarely if ever lead to satisfaction and may even lead to greater distress with the perception of new defects attributed to the surgery.

Differential Diagnosis
The preoccupations of body dysmorphic disorder must first be differentiated from usual concerns with grooming and appearance. Attention to appearance and grooming is universal and socially sanctioned. However, diagnosis of body dysmorphic disorder requires that the preoccupation cause clinically significant distress or impairment. In addition, in body dysmorphic disorder, concerns focus on an imaginary or exaggerated defect, often of something, such as a small blemish, that would warrant scant attention even if it were present. Persons with histrionic personality disorder may be vain and excessively concerned with appearance. However, the focus in this disorder is on maintaining a good or even exceptional appearance, rather than preoccupation with a defect. Such concerns are probably unrelated to body dysmorphic disorder. In addition, by nature, the preoccupations in body dysmorphic disorder are essentially unamenable to reassurance from friends or family or consultation with physicians, cosmetologists, or other professionals.

Next, the possibility of an explanation by a general medical condition must be considered (see Figure 74–1). As mentioned, patients with this disorder often first present to plastic surgeons, oral surgeons, and others, seeking correction of defects. By the time a mental health professional is consulted, it has generally been ascertained that there is no physical basis for the degree of concern. As with other syndromes involving somatic preoccupations (or delusions), such as olfactory reference syndrome and delusional parasitosis (both included under delusional disorder, somatic type), occult medical conditions, such as an endocrine disturbance or a brain tumor, must be excluded.

In terms of explanation on the basis of another psychiatric disorder, there is little likelihood that symptoms of body dysmorphic disorder will be intentionally produced as in malingering or factitious disorder. Unlike in other somatoform disorders, such as pain, conversion, and somatization disorders, preoccupation with appearance predominates. Somatic preoccupations may occur as part of an anxiety or mood disorder. However, these preoccupations are generally not the predominant focus and lack the specificity of dysmorphic symptoms. Because patients with body dysmorphic disorder often become isolative, social phobia may be suspected. However, in social phobia, the person may feel self-conscious generally but will not focus on a specific imagined defect. Indeed, the two conditions may coexist, warranting both diagnoses. Diagnostic problems may present with the mood-congruent ruminations of major depression, which sometimes involve concern with an unattractive appearance in association with poor self-esteem. Such preoccupations generally lack the focus on a particular body part that is seen in body dysmorphic disorder. On the other hand, patients with body dysmorphic disorder commonly have dysphoric affects described by them variously as anxiety or depression.

Differentiation from schizophrenia must also be made. At times, a dysmorphic concern will seem so unusual that such a psychosis may be considered. Furthermore, patients with this disorder may show ideas of reference in regard to defects in their appearance, which may lead to the consideration of schizophrenia. However, other bizarre delusions, particularly of persecution or grandiosity, and prominent hallucinations are not seen in body dysmorphic disorder. From the other perspective, schizophrenia with somatic delusions generally lacks the focus on a particular body part and defect. Also in schizophrenia, with somatic delusions generally lacks the focus on a particular body part and defect. Also in schizophrenia, bizarre interpretations and explanations for symptoms are often present, such as “this blemish was a sign from Jesus that I am to protect the world from Satan.” Other signs of schizophrenia, such as hallucinations and disorganization of thought, are also absent in body dysmorphic disorder. As previously mentioned, the preoccupations in body dysmorphic disorder appear to be on a continuum from full insight to delusional intensity whereby the patient cannot even consider the possibility that the preoccupation is groundless. In such instances, both body dysmorphic disorder and delusional disorder, somatic type, are to be diagnosed.

Body dysmorphic disorder is not to be diagnosed if the concern with appearance is better accounted for by another psychiatric disorder. Anorexia nervosa, in which there is dissatisfaction with body shape and size, is specifically mentioned in the criteria as an example of such an exclusion. DSM-III-R also mentioned transsexualism (gender identity disorder in DSM-IV-TR) such as a disorder. Although not specifically mentioned in DSM-IV-TR, if a preoccupation is limited to discomfort or a sense of inappropriateness of one’s primary and secondary sex characteristics, coupled with a strong and persistent cross-gender identification, body dysmorphic disorder is not diagnosed.

The preoccupations of body dysmorphic disorder may resemble obsessions and ruminations as seen in obsessive–compulsive disorder. Unlike the obsessions of
obsessive–compulsive disorder, the preoccupations of body dysmorphic disorder focus on concerns with appearance. Compulsions are limited to checking and investigating the perceived physical defect and attempting to obtain reassurance from others regarding it. Still, the phenomenology is similar, and the two disorders are often comorbid. If additional obsessions and compulsions not related to the defect are present, obsessive–compulsive disorder can be diagnosed in addition to body dysmorphic disorder.

**Etiology and Pathophysiology**

A number of sociological, psychological, and neurobiological theories have been proposed. Body dysmorphic disorder has been explained, at least in part, as an exaggerated incorporation of societal ideals of physical perfection and acceptance of cosmetic plastic surgery to attain such goals. A high frequency of insecure, sensitive, obsessional, schizoid, anxious, narcissistic, introverted, and hypochondriacal personality traits in body dysmorphic patients have been described (Phillips 1991). Various psychodynamic mechanisms and symbolic meanings of dysmorphic symptoms have been suggested (Phillips 1991), going back to Freud’s case of the Wolfman who had dysmorphic preoccupations regarding his nose.

Some interesting neurobiological possibilities have emerged, particularly concerning observations that hypochondriasis, body dysmorphic disorder, and a number of other conditions involving compelling repetitive thoughts or behaviors may respond preferentially to SSRIs, not to other antidepressant drugs. An obsessive–compulsive spectrum disorders grouping, the pathological process of which is mediated by serotonergic dysregulation, has been suggested. As further evidence, symptoms of body dysmorphic disorder as well as those of obsessive–compulsive disorder may be aggravated by the partial serotonin agonist m-chlorophenylpiperazine (Hollander et al. 1992).

**Treatment**

**Psychosocial and Somatic Treatments**

First, the generic goals and treatments as outlined for the somatoform disorders overall should be instituted. These are beneficial in interrupting an unending procession of repeated evaluations and the possibility of needless surgery, which may lead to additional perceptions that surgery has resulted in further disfigurement. Phillips and Diaz (1997) reported that 83% (of 139 patients) who received surgical, dermatological, or other nonpsychiatric treatment reported worsening or no change in symptoms.

Traditional insight-oriented therapies have not generally proved to be effective. Results with traditional behavioral techniques, such as systematic desensitization and exposure therapy, have been mixed. At least without amelioration with effective pharmacotherapy, the preoccupations do not extinguish as would be expected with phobias. A cognitive–behavioral approach similar to what was recommended for hypochondriasis may be more effective. This includes response prevention techniques whereby the patient is not permitted to repetitively check the perceived defect in mirrors. In addition, patients are advised not to seek reassurance from family and friends, and these persons are instructed not to respond to such inquiries. Some patients adopt such behaviors spontaneously, avoiding mirrors and other reflecting surfaces, refusing even to allude to their perceived defects to others. Such “self-techniques” may be encouraged and refined. There remains a paucity of randomized controlled trials, particularly directly comparing treatments.

Biological treatments have long been used but until recently were of limited benefit to patients with body dysmorphic disorder. Approaches have included electroconvulsive therapy, tricyclic and MAOI antidepressants, and neuroleptics (particularly pimozide) (Andreasen and Bardach 1977). In most reports of positive response to tricyclic or MAOI antidepressant drugs, it is unclear whether response was truly in terms of the dysmorphic syndrome or simply represented improvement in comorbid depressive or anxiety syndromes. Response to neuroleptic treatment has been suggested as a diagnostic test to distinguish body dysmorphic disorder from delusional disorder, somatic type (Riding and Munro 1975). The delusional syndromes often respond to neuroleptics; body dysmorphic disorders, even when the body preoccupations are psychotic, generally do not. Pimozide has been singled out as a neuroleptic with specific effectiveness for somatic delusions, but this specificity does not appear to apply to body dysmorphic disorder.

An exception to this uninspiring picture is the observation of a possible preferential response to antidepressant drugs with serotonin reuptake blocking effects, such as clomipramine, or SSRIs, such as fluoxetine and fluvoxamine (Hollander et al. 1992, Hollander et al. 1999). Phillips et al. (1993) reported that more than 50% of patients with body dysmorphic disorder showed a partial or complete remission with either clomipramine or fluoxetine, a response not predicted on the basis of coexisting major depressive or obsessive–compulsive disorder. As with hypochondriasis, effectiveness is generally achieved at levels recommended for obsessive–compulsive disorder rather than for depression (e.g., 60–80 mg/day rather than 20–40 mg/day of fluoxetine). The SSRIs appear to ameliorate delusional as well as nondelusional dysmorphic preoccupations. Successful augmentation of clomipramine or SSRI therapy has been suggested with buspirone, another drug with serotonergic effects. Neuroleptics, particularly pimozide, may also be helpful adjuncts, particularly if delusions of reference are present. Little seems to be gained with the addition of anticonvulsants, or benzodiazepines to the SSRI therapy.

As yet, rigorous studies have not been conducted, but anecdotal observations and open-label studies show promise for effective treatment with SSRIs and other serotoninergic agents for this, until now, therapeutically exasperating disorder. If such approaches fulfill their initial promise, integrated approaches using pharmacotherapy and other modalities such as CBT may provide effective treatment options.

---

**Clinical Vignette 6**

A 22-year-old single woman who lived with her parents was referred for psychiatric consultation because of preoccupations of 4 years that there was something wrong with the way her teeth were situated in her jaw. She could not specify what exactly was wrong but insisted that her teeth felt “funny” and at times would actually relocate.
SOMATOFORM DISORDER NOS

Definition and Diagnostic Features

Somatoform disorder NOS is the true residual category for this group of disorders. By definition, disorders considered under this category are characterized by somatic symptoms, but criteria for any of the specific somatoform disorders are not met. Several examples are given, but syndromes potentially included under this category are not limited to these. Unlike for undifferentiated somatoform disorder, no minimal duration is required. This category was incorporated into DSM-III-R, replacing the DSM-III atypical somatoform disorder, a residual category requiring that physical symptoms and complaints not be explained on the basis of demonstrable organic findings or a known pathophysiological mechanism and that they were “apparently linked to psychological factors.” The only example given was dysmorphephobia. DSM-III-R similarly required that criteria for any specific somatoform or adjustment disorder with physical symptoms not be met. Examples given were nonpsychotic hypochondriacal symptoms and non-stress-related physical complaints of less than 6 months’ duration. DSM-IV-TR lists as examples pseudocyesis, disorders involving hypochondriacal complaints but of less than 6 months’ duration, and disorders involving unexplained physical complaints such as fatigue or body weakness not due to another mental disorder and again of less than 6 months’ duration. This last syndrome would seem to resemble neurasthenia of short duration, a syndrome with a long historical tradition with inclusion in DSM-II, ICD-9, and ICD-10. Neurasthenia was considered for inclusion as a separate DSM-IV-TR somatoform disorder. Reasons that it was not included in DSM-IV-TR include difficulties in delineating it from depressive and anxiety disorders and from other somatoform disorders. If included, neurasthenia could have become a clinical “wastebasket” that could facilitate premature closure of diagnostic inquiry, such that
Clinical Vignette 7

A 64-year-old man was referred for psychiatric consultation by a gastroenterologist because of the patient’s uncompromising preoccupation of 4 months that he suffered from colon cancer. This fear developed after the patient underwent lower bowel radiography to evaluate complaints of constipation unimproved with dietary changes, stool softeners, and laxatives. He was allowed to view his radiographs, and he noted a “shadow” that he was convinced represented a cancer mass. The patient was then shown the film with explicit explanation. He was satisfied temporarily, but he soon became concerned that if it was not cancer, a rubber tube may have been left in his colon from the barium enema examination and, if left there, would eventually cause cancer. The patient could consider that his concern might be unfounded, yet “I just can’t shake the idea that I have cancer.” The patient had no other unusual ideas or prominent symptoms. He denied feeling sad and was not worried about other things. He did feel that “this is draining all my energy” and had difficulty in concentrating on any of his usual interests or hobbies. He did not feel guilty about anything and was not contemplating suicide or wishing to be dead, but “I just know this thing is going to kill me!” He had no prior history of excessive health concerns and had never felt any need for psychiatric treatment.

The psychiatrist’s diagnosis was (1) possible somatoform disorder NOS, consider hypochondriasis early in its course, but ruled out major depressive disorder or delusional disorder, somatic type, as alternative explanations; (2) ruled out occult general medical condition underlying his complaints: a gastrointestinal disorder with subtle symptoms and no objective findings; depressive disorder NOS; delusional disorder, somatic type; or mental disorder NOS due to a general medical condition. It was recommended that the patient be (1) thoroughly evaluated for a general medical condition, including endocrine studies, and (2) empirically started on an SSRI.

This clinical vignette illustrates an important aspect of somatoform disorder NOS. In using this diagnosis, the psychiatrist must remain cognizant that it is a residual category, and vigilance must be maintained for the emergence of a previously undetected general medical or psychiatric condition.

Differential Diagnosis

As a residual category, somatoform disorder NOS is to be diagnosed after all other possibilities are excluded (see Figure 74–1). After it is determined that a syndrome with somatoform symptoms is not attributable to a nonsomatoform psychiatric disorder and does not meet criteria for any of the specific somatoform disorders (including, on the symptom-focused side, pain, conversion, and somatization disorders and, on the preoccupation-focused side, hypochondriasis or body dysmorphic disorder), the two diagnostic possibilities that remain are undifferentiated somatoform disorder and somatoform disorder NOS. Except in the case of pseudocyesis, these two are differentiated on the basis of whether the disturbance is of 6 months’ duration. If symptoms last more than 6 months, undifferentiated somatoform disorder is diagnosed; if less than 6 months, somatoform disorder NOS.

CONCLUSION

As a group, the syndromes now subsumed under the rubric of somatoform disorders are relatively common and are associated with great direct and indirect costs to society. Yet, they have remained a “stepchild” of psychiatry, underdiagnosed and underresearched. Perhaps the first step in bringing these conditions into the light was the formalization of criteria and nomenclature and their aggregation into a group in DSM-III. This has allowed a practical approach to the differential diagnosis of conditions with physical symptoms suggestive of underlying general medical conditions (see Figure 74–1). Moreover, the definition of this group has been conducive to more coordinated research in which findings are more comparable from one investigation to another. With this, therapeutic direction is emerging, with some general guidelines for all of these disorders, some specific ways of managing patients with somatization disorder, undifferentiated somatoform disorder, and conversion disorder, and a more utilitarian approach to management of patients with pain disorders.
It appears that pharmacological inroads are being made in the treatment of hypochondriasis and body dysmorphic disorder in terms of the possible efficacy of SSRIs. This pharmacological “probe” suggests that these disorders may be more closely linked with the so-called obsessive–compulsive spectrum disorders (Hollander 1993) than with the other somatoform disorders, a linkage that may be reflected in future diagnostic systems. Even if this turns out to be the case, the somatoform disorder concept will have served its purpose in stimulating and making possible research leading to a better understanding and ultimately more effective treatments for these complex conditions.

Much work remains to be done before the knowledge concerning the somatoform disorders and their treatment catch up with the understanding of other groupings of psychiatric disorders.

Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research for Somatization Disorder has both a different item set and algorithm. Six symptoms are required out of a list of 14 symptoms, which are broken down into the following groups: 6 gastrointestinal symptoms, 2 cardiovascular symptoms, 3 genitourinary symptoms, and 3 “skin and pain” symptoms. It is specified that the symptoms occur in at least two groups. In contrast, DSM-IV-TR requires 4 pain symptoms, 2 gastrointestinal symptoms, 1 sexual symptom, and 1 pseudoneurological symptom. Furthermore, the ICD-10 Diagnostic Criteria for Research specify that there must be “persistent refusal to accept medical reassurance that there is no adequate physical cause for the physical symptoms.” DSM-IV-TR only requires that the symptoms result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning and that the symptoms cannot be fully explained by a known general medical condition or substance. For Undifferentiated Somatoform Disorder, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical.

Regarding conversion disorder, ICD-10 considers conversion a type of dissociative disorder and includes separate criteria sets for dissociative motor disorders, dissociative convulsions, and dissociative anesthesia and sensory loss in a section that also includes dissociative amnesia and dissociative fugue.

For pain disorder, the ICD-10 Diagnostic Criteria for Research require that the pain last at least 6 months and that it not be “explained adequately by evidence of a physiological process or a physical disorder.” In contrast, DSM-IV-TR does not force the clinician to make this inherently impossible judgment and instead requires the contribution of psychological factors. Furthermore, DSM-IV-TR includes both acute (duration less than 6 months) and chronic pain (more than 6 months). This disorder is referred to in ICD-10 as “Persistent Somatoform Pain Disorder.”

ICD-10 provides a single criteria set that applies to both the DSM-IV-TR categories of hypochondriasis and body dysmorphic disorder. The ICD-10 Diagnostic Criteria for Research for Hypochondriasis specifies that the belief is of a “maximum of two serious physical diseases” and requires that at least one be specifically named by the individual with the disorder. The DSM-IV-TR has no such requirement.

Section VI • Disorders

Introduction

Patients with factitious disorder consciously induce or feign illness in order to obtain a psychological benefit from being in the sick role. They usually have little insight into the motivations of their behaviors but are still powerfully driven to appear ill to others. In many cases, they endanger their own health and life in their desire to appear sick. Patients with this disorder will often induce serious illness or undergo numerous unnecessary, invasive procedures. As most people avoid sickness, the actions of these patients appear to run counter to human nature. Also, since entry into the "sick role" requires that the sick person should try to get better, patients with factitious disorder must conceal the voluntary origin of their symptoms. The inexplicability of their actions combined with their deceptive behavior stir up both intense interest and intense (usually negative) countertransference in health care providers.

Parsons (1951) described the "sick role" and noted that in our society there are four aspects of this role. First, the patient is not able to will himself or herself back to health but instead must “be taken care of.” Second, the patient in the sick role must regard the sickness as undesirable and want to get better. Third, the sick patient is obliged to seek medical care and cooperate with his or her medical treatment. Finally, the sick patient is exempted from the normal responsibilities of his or her social role.

It is the conscious awareness of the production of symptoms that differentiates factitious disorder from the somatoform disorders. Patients with somatoform disorders are unaware of the psychological origins of their symptoms, and they genuinely believe themselves to be ill. In contrast, it is the underlying motivation to produce symptoms that separates factitious disorders from malingering. Patients who malingers consciously feign or induce illness in order to obtain some external benefit (such as money, narcotics, or excuse from duties) as opposed to the internal, psychological motivation of a patient with factitious disorder. While the distinctions among these disorders appear satisfyingly clear, in practice, patients often blur the boundaries. Patients with somatoform disorders will sometimes consciously exaggerate symptoms which they have unconsciously produced, and it is a rare patient who consciously creates illness and yet receives no external gain at all, be it disability benefits, excuse from work, or even food and shelter.

While physicians have known about the feigning of illness since at least ancient Greece (Feldman 2000), it is likely that Asher’s (1951) article brought the concept of factitious illness into general medical knowledge. Asher coined the term Munchausen’s syndrome referring to the Baron von Munchausen, a character in German literature who was known for greatly exaggerating the tales of his exploits. (The use of this term may be somewhat unfair to the baron. Apparently, Rudolf Raspe, his unauthorized biographer, may have greatly overstated both the Baron’s exploits and his tendency to exaggerate (Guziec et al. 1994)). Asher described Munchausen’s syndrome as severe, chronic factitious disorder combined with antisocial behavior including wandering from hospital to hospital (peregrination). However, his memorable term has often been used interchangeably with “factitious disorder” and incorrectly applied to patients with less severe forms of the disease.

Patients have been known to create or feign numerous illnesses, both acute and chronic, in all of the medical specialties. It appears that the only limit is the creativity and knowledge of a given patient. In fact, there is at least one case report of a patient who feigned factitious disorder itself (Gurwith and Langston 1980). The patient claimed to have Munchausen’s syndrome, to have undergone numerous unnecessary procedures and operations, and as a result, to need immediate hospitalization. He displayed his abdomen, which appeared to have numerous surgical scars and hinted that searches of his hospital room would be fruitful. However, collateral information revealed that the physicians and hospitals he had reported had never treated the patient, and his “scars” washed off with soap and water. Patients with factitious disorder are often quite medically sophisticated. Even though acquired immune deficiency syndrome was not described until the early 1980s, the first factitious cases...
followed shortly thereafter, at least as early as 1986 (Miller et al. 1986). Some individuals pursue the sick role not by feigning illness in themselves, but instead by creating it in another person, usually someone dependent on the perpetrator. They seek the role of caring for an ill individual and are diagnosed with factitious disorder by proxy.

**Factitious Disorder**

**Definition and Diagnostic Features**

For a diagnosis of factitious disorder (see *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) criteria for factitious disorder) to be justified, a person must be intentionally producing illness; his or her motivation is to occupy the sick role, and there must not be external incentives for the behavior. While the DSM is clear that no external incentives can be present to meet the criteria for the diagnosis, it is rarely the case that there is absolutely no secondary gain for a patient (as the sick role automatically conveys some external benefits such as release from usual duties). In practice, clinicians will often diagnose patients with factitious disorder in the presence of some external gain as long as the external benefits do not appear to be a major motivation for the production of symptoms. Of course, some patients muddy the distinction between factitious disorder and malingering, as they appear to be motivated both by seeking the sick role and by powerful external motivations. For example, Eisendrath and McNeil (2004) reported four cases of patients involved in civil litigation (an external incentive in the form of a monetary reward), yet their factitious illnesses continued after the litigation was complete and resulted in the patients’ deaths. Some authors have complained about the inherent subjectivity in defining a diagnosis in part by the patient’s motivation (and therefore involving some speculation by the clinician) (Turner 2006), however, as the distinction between malingering and factitious disorder rests on the internal motivation of the patient, it is impossible to escape this subjectivity, at least with the current definitions. Patients who readily admit to inducing symptoms, such as self-mutilating patients, are not diagnosed with factitious disorder as they are not creating their symptoms to occupy the sick role. The diagnosis of factitious disorder (Figure 75–1) is subclassified, depending on whether the factitious symptoms are predominantly psychological, physical, psychological, or a combination of both.

Due to the inherently deceptive nature of patients with factitious disorder, the literature is largely confined to case reports and case series. It is likely that many patients with less severe forms of the disease escape detection, and their clinical characteristics might be quite different.

**Factitious Disorder with Predominant Physical Signs and Symptoms**

Patients with this subtype of factitious disorder present with physical signs and symptoms. The three main methods patients use to create illness are: (1) giving a false history, (2) faking clinical and laboratory findings, and (3) inducing illness (e.g., by surreptitious medication use, inducing infection, or preventing wound healing) (Eisendrath 1994). There are reports of factitious illnesses in all of the medical specialties. Particularly common presentations include fever, self-induced infection, gastrointestinal symptoms, impaired wound healing, cancer, renal disease (especially hematuria and nephrolithiasis), endocrine diseases, anemia, bleeding disorders, and epilepsy (Wise and Ford 1999). True Munchausen’s syndrome fits within this subclass and is the most severe form of the illness. According to the DSM-IV-TR, patients with Munchausen’s syndrome have chronic factitious disorder with physical signs and symptoms, and in addition, have a history of recurrent hospitalization, peregrination, and pseudologia fantastica—dramatic, untrue, and extremely improbable tales of their past experiences (American Psychiatric Association 2000). They are often very familiar with hospital procedure and use this knowledge to present dramatically during off-hours or at house officer transition times when the factitious nature of their symptoms is least likely to be discovered.

**Code based on type**

300.16 With Predominantly Psychological Signs and Symptoms: if psychological signs and symptoms predominate in the clinical presentation 300.19 With Predominantly Physical Signs and Symptoms: if physical signs and symptoms predominate in the clinical presentation 300.19 With Combined Psychological and Physical Signs and Symptoms: if both psychological and physical signs and symptoms are present and neither predominates in the clinical presentation

**Factitious Disorder with Predominantly Psychological Signs and Symptoms**

Another subtype of factitious disorder includes patients who present feigning psychological illness. They both report and mimic psychiatric symptoms. There are reports of factitious psychosis, posttraumatic stress disorder, homicidal ideation, and alcohol dependence (Pope et al. 1982, Sparr and Pankratz 1983, Mitchell and Francis 2003, Thompson and Beckson 2004), and it is likely that patients feign psychiatric disorders across the full spectrum of mental illness. In addition, there are reports of false claims of being a victim of stalking or rape (Pathe et al. 1999, Feldman et al. 1994), and these cases are often diagnosed with a factitious psychological disorder such as posttraumatic stress disorder.
While patients with factitious psychological symptoms feign psychiatric illness, they also often suffer from true comorbid psychiatric disorders, particularly Axis II disorders and substance abuse, and case reports suggest that patients with psychological factitious disorder have a high rate of suicide and a poor prognosis (Eisendrath 2001, Pope et al. 1982, Popli et al. 1992). While Munchausen’s syndrome is considered a subset of physical factitious disorder, there are case reports of patients presenting with psychological symptoms who also have some of the key features of Munchausen’s (pathological lying, wandering, and recurrent hospitalizations) (Merrin et al. 1986, Popli et al. 1992).

**Factitious Disorder with Combined Psychological and Physical Signs and Symptoms**

DSM-III separated factitious disorder into two disorders, based on whether the symptoms were physical or psychological. However, case reports clarified that this distinction was often artificial (Merrin et al. 1986, Parker 1993). Some patients present with simultaneous psychological and physical factitious symptoms, and some patients move between physical and psychological presentations over time. DSM-IV-TR was revised to account for patients who present with both psychological signs and symptoms, though this category of patients is the least well studied.

---

**Clinical Vignette 1**

**Munchausen’s Syndrome**

A 42-year-old man was brought in by ambulance from a public park after complaining of shortness of breath and collapsing. Onlookers called 911. In the emergency room, the patient complained of shortness of breath and chest pain. He reported that he had a history of multiple pulmonary emboli necessitating Greenfield filter placement. He seemed to be very familiar with the medical terminology and clinical findings in pulmonary emboli. The patient had an extensive workup including a high resolution CT scan, but all studies were normal. The medical team noted that the patient appeared to be holding his breath when his oxygen saturation was being measured, and in addition, was performing a Valsalva maneuver during his ECGs. The medical resident attempted to clarify the patient’s history by obtaining collateral information. The hospitals contacted reported that the patient had presented numerous times with the same complaints, and there had been suspicion of a factitious disorder. The medical resident informed the patient of the conflicting information, at which point the patient became very angry and immediately left the hospital. He was lost to follow up.
Factitious Disorder with Psychological Features

A 46-year-old man presented complaining of symptoms of posttraumatic stress disorder (PTSD). He reported intense flashbacks, numbing and avoidance, and irritability resulting from his experience as a combat veteran. He began intensive treatment for PTSD including support groups, individual therapy, and medication management. He was an extremely active participant in the support groups and would recount detailed horrors of his time in combat. A staff member verifying the patient’s history learned the patient had served in the military but was not a combat veteran. The patient was confronted in a supportive manner, and he admitted that he had fabricated his history. It was recommended that the patient would continue in psychiatric treatment, and he agreed to do so.

Assessment

The diagnosis of factitious disorder is made in several ways. Factitious disorder is occasionally diagnosed accidentally when the patient is discovered in the act of creating symptoms. A history of inconsistent or unexplainable signs and symptoms or failure to respond to appropriate treatment can prompt health care providers to probe for evidence of the disorder, as can evidence of peregrination or pathological lying. In some cases, it is a diagnosis of exclusion in an otherwise inexplicable case. In order to make the diagnosis, it is necessary to consider it in the differential of the patient’s illness; however, physicians are often hesitant to suspect that their patients may be deceiving them. Given that the prevalence of factitious disorder may be over 1% of the inpatient population, physicians should probably include it on the differential in medically complex cases more frequently than is now done, as this would allow for a careful investigation of the possibility of factitious disorder along with the other possible diagnoses. However, it would be important to clarify to other members of the treatment team that it is just one diagnosis of several that is being considered given the significant countertransference issues that can arise in dealing with factitious disorder.

If there is suspicion of factitious disorder, confirmation can be difficult. Laboratory examination can confirm some factitious diagnoses such as exogenous insulin or thyroid hormone administration. Collateral information from family members or previous health care providers is often extremely helpful. Factitious disorder with psychological signs and symptoms can be particularly difficult to diagnose, as so much of psychiatric diagnosis relies on the patient’s report. However, there is some evidence that neuropsychological testing may be helpful in making the diagnosis. Both McCaffrey and Bellamy-Campbell (1989) and Fairbank et al. (1985) report the ability to detect over 90% of cases of factitious PTSD using the Minnesota multiphasic personality inventory (MMPI). However, Perconte and Goreczny (1990) were unsuccessful in attempting to replicate the findings. In addition, there is a report of MMPI-test-results being used to support a diagnosis of factitious disorder with psychological features in a woman thought to be feigning symptoms of multiple personality disorder (Coons 1993).

Epidemiology

The nature of factitious disorder makes it difficult to determine how common it is within the general population. Patients attempt to conceal themselves, thereby artificially lowering the prevalence. The tendency of patients to present several times at different facilities, however, may artificially raise the prevalence. Most estimates of the prevalence of the disease, therefore, rely on the number of factitious patients within a given inpatient population. Such attempts have generated estimates that 0.5–3% of medical and psychiatric inpatients suffer from factitious disorder. Of 1,288 patients referred for psychiatric consultation at a Toronto general hospital, 10 (0.8%) were diagnosed with factitious disorder (Sutherland and Rodin 1990). A prospective examination of all 1,538 patients hospitalized in a Berlin neurology department over 5 years found five (0.3%) cases of factitious disorder (Bauer and Boegner 1996). An examination of 506 patients with fever of unknown origin (FUO) revealed that 2.2% of the fevers were of factitious origin (Rumans and Vosti 1978), and a review of 199 Belgian patients with FUO found 7 of 199 (3.5%) to be factitious (Knockaert and Vosti 1978). A similar study of patients with FUO at the National Institutes of Health (NIH) revealed that 9.3% of the fevers were factitious (Aduan et al. 1979). The increased prevalence found at the NIH may be due to the fact that the study was undertaken in a more tertiary setting, and it is a reminder that the prevalence of factitious disorder likely varies widely depending on the population and the setting. Gault et al. (1988) examined 3,300 renal stones brought in by patients and found that 2.6% of these stones were mineral and felt to be submitted by factitious or malinger patients. There is much less data on the prevalence of factitious disorder with psychological features. A study of psychiatric inpatients showed a prevalence of 0.5% of admissions determined to be a result of a factitious psychological condition (Bhugra 1988). There are few data about the prevalence of factitious disorder in an outpatient population. Because factitious patients do not readily identify themselves in large community surveys, it is not currently possible to determine the prevalence of the disorder in the general population.

Comorbidity Patterns

All types of factitious disease show a strong association with substance abuse (Kent 1994) as well as borderline and narcissistic personality disorders. In a case series by Ehlers and Plassman (1994), 9 of 18 patients had personality features that met criteria for borderline personality disorder, and another 6 of 18 had personality features that met criteria for narcissistic personality disorder. In a series of 93 patients with factitious disorder, Krahn et al. (2003) found that 32% of the patients had a second DSM-IV-TR diagnosis and that 33% had a chemical dependency. Analyses of reported cases of patients with factitious disorder by proxy have found a high incidence (approximately one-fourth to one-third) of comorbidity with personal factitious disorder or factitious features (Sheridan 2003, Rosenberg 1987). There is not any data on the reverse, that is, how many patients with factitious disorder also have factitious disorder by proxy, but it is worth being alert to the possibility that a patient with factitious disorder might also be inducing illness in a dependent.
Course
Numerous reports (Carney and Brown 1983, Reich and Gottfried 1983, Wise and Ford 1999) in the literature describe two different subclasses of factitious patients, and the course for each subclass is quite different. The first type fits with the classic Munchausen's syndrome diagnosis: they have chronic factitious symptoms associated with antisocial traits, pathological lying, minimal social supports, and poor work and relationship functioning. Patients with Munchausen’s syndrome appear of having an extremely poor prognosis (Eisendrath 2001, Carney and Brown 1983). Fortunately, this most severe class of patients makes up the minority of factitious patients, probably fewer than 10%.

The second and more typical type of patient does not display pathological lying or wandering. Their recurrent presentations are usually within the same community, and they become well known within the local health care system. They often have stable social supports and employment, and a history of a medically related job. This larger class of factitious patients is more likely to accept psychiatric treatment and to show improvement. There are individuals who may have an episode of factitious disorder in reaction to a life stressor, but may return to premorbid functioning after the stressor is resolved (Goldstein 1998).

The course of untreated factitious disorder is variable. Patients with factitious disorder commonly suffer a great deal of morbidity, both physical and psychological, and some cases can be fatal. One survey of 41 cases noted only one fatality, though many of the other cases were life-threatening (Reich and Gottfried 1983). Another retrospective report noted two fatalities out of 28 patients for whom they had the follow-up data (out of 93 total patients)—though they did not report if it was thought that these deaths were due to the factitious illness (Krahn et al. 2003). Eisendrath and McNeil (2002 and 2004) reported that of a series of 20 factitious patients who were involved with civil litigation, there were four deaths, all of which occurred as a direct result of the factitious illness. Patients with psychological signs and symptoms are reported to have a high rate of suicide and a poor prognosis (Pope et al. 1982, Popli et al. 1992).

Differential Diagnosis
The differential diagnosis of factitious disorder includes rare or complex physical illnesses, somatoform disorders, malingering, other psychiatric disorders, and substance abuse (McKane and Anderson 1997). It is especially important to rule out genuine physical illness since complex medical illnesses can be mistaken for factitious disorder, and because patients with factitious disorder often induce real physical illness.

Differences in Developmental, Gender, and Cultural Presentations
Factitious patients span a broad age-range. Reports in the literature show patients ranging from 8 to 85 years (Absolut de la Gastine et al. 1998, Davis and Small 1985). Of note, there is a report of a 4-year-old patient thought to have factitious disorder but who reported that he had been coached by his mother and may be better diagnosed as a victim of factitious disorder by proxy (Croft and Jervis 1989). Case series suggest that the majority of people with factitious disorder are women—one case series found 78% of patient to be women (Plasmsmann 1994a) and another 72% (Krahn et al. 2003) while the majority of patients with the more severe Munchausen variant are men. A case series of patients with cardiac Munchausen’s syndrome (who had an average of six hospitalizations) found that 54% were men (Mehta and Kahn 2002). Ethnicity is frequently not reported in case studies and series, so it is difficult to determine if there are any ethnic differences in the prevalence or presentation of factitious disorder. In Krahn et al.’s (2003) review of 93 patients with factitious disorder who presented to the Mayo Clinic, 84% were Caucasian and 2% were African-American with the remaining 7% of other races (Krahn et al. 2003). However, as these patients were drawn from a population that presented to a tertiary care center in Minnesota, it is not likely the representative of the general population. While cases of factitious disorder have been reported worldwide, it is not known if the presentation varies from culture to culture (though it would not be surprising as the construct of the sick role does vary culturally).

Etiology and Pathophysiology
Genetic Factors
While factitious disorder appears to run in families, it is not known if this is explainable by genetic factors, environmental factors or both.

Neurobiological Factors
The presence of central nervous system (CNS) abnormalities in some patients with factitious disorders have led some to hypothesize that underlying brain dysfunction contributes to factitious disorder. One review of factitious patients with pseudologia fantastica found CNS abnormalities (such as EEG abnormality, head injury, imaging abnormalities, or neurological findings) in 40% of the patients (King and Ford 1988). There have been case reports of magnetic resonance imaging (MRI) (Fenelon et al. 1991) and single photon emission computed tomography (SPECT) (Mountz et al. 1996) abnormalities, but it is unknown if these abnormalities were related to the disorder.

Psychological Factors
Patients with factitious disorder create illness in pursuit of the sick role. For these patients, being in the sick role may allow them to compensate for an underlying psychological deficit. Most authors identify several common psychodynamic motivations for factitious disorder (Feldman 2000, Eisendrath 2001, Guzic et al. 1994, Folks 1995, Hyler and Sussman 1981). First, patients with little sense of self may seek the sick role in order to provide a well-defined identity around which to structure themselves. Others may seek the sick role in order to meet dependency needs which have gone unmet elsewhere. As a patient, they receive the attention, caring, and nurturing of the health care environment and are relieved of many of their responsibilities. In addition, some patients may engage in factitious behaviors for masochistic reasons. They feel that they deserve punishment for some forbidden feelings and thus they should suffer at the hands of their physicians. Other patients may be motivated by anger at physicians and dupe them in retaliation. Patients with a history of childhood illness or abuse may attempt to master
past traumas by creating a situation over which they have control. Finally, some authors have speculated that some patients may be expressing suicidal wishes through their factitious behavior (Schoenfeld et al. 1987, Roy and Roy 1995).

Social and Environmental Factors
In addition, childhood developmental disturbances are thought to contribute to factitious disorder. Predisposing factors are thought to include (1) serious childhood illness or illness in a family member during childhood, especially if the illness was associated with attention and nurturing in an otherwise distant family, (2) past anger with the medical profession, (3) past significant relationship with a health care provider, and (4) factitious disorder (especially factitious disorder by proxy) in a parent (McKane and Anderson 1997). It is thought that factitious disorder is more common in people in the health care professions, though it is not known if working in health care increases the risk for developing factitious disorder or if people with factitious disorder are drawn to health care work.

Treatment

Treatment Goals
The goals in treating patients with factitious disorder are twofold: first to minimize the damage done by the disorder to both the patient’s own health and the health care system, and second, to help patients recover, at least partially, from the disorder. These goals are furthered by treating comorbid medical illnesses, avoiding unnecessary procedures, encouraging patients to seek psychiatric treatment, and providing support for health care clinicians. As mentioned before, patients with true Munchausen’s syndrome (including antisocial traits, pathological lying, wandering, and poor social support) are felt to be refractory to treatment. While factitious disorder is extremely difficult to cure, effective techniques exist to minimize morbidity, and some patients are able to benefit greatly from psychiatric intervention.

Somatic Treatments
It is extremely important to treat any comorbid medical illnesses as patients with factitious disorder often induce genuine medical illness, and patients with factitious disorder are not immune to the physical illnesses that plague the general population. As much as possible, providers should base medical treatment on objective physical and laboratory signs and avoid unnecessary procedures. There are no clear data supporting the effectiveness of medications in treating factitious disorder. There is a case report of effective pimozide treatment in a patient thought to have delusional symptoms (Prior and Gordon 1997) as well as a case report of a factitious patient with comorbid depression improving when treated with an antidepressant in addition to intensive psychotherapy (Earle and Folks 1986).

Psychosocial Treatments
Soon after Asher’s (1951) article was published, many patients with factitious disorder were vigorously confronted once the nature of their illness was discovered. Unfortunately, most patients would deny their involvement and seek another provider who was unaware of their diagnosis (Eisendrath 2001). In addition, the idea of “blacklists” was proposed in order to aid detection of these patients. However, issues regarding patient confidentiality, as well as concerns about cursory medical evaluations that might miss genuine physical illness, prevented this idea from being adopted (Eisendrath 2001). Although aggressive confrontation is usually unsuccessful, supportive, nonpunitive confrontation may be helpful for some. In one case series, 33 patients were confronted with the factitious nature of their illness. While only 13 admitted feigning illness, most of the patients’ illnesses subsequently improved, at least in the short term (Reich and Gottfried 1983).

Eisendrath suggested three alternatives to confrontation that he found effective. First is inexact interpretation, in which the psychiatrist interprets the psychodynamics thought to be underlying the patient’s behavior without explicitly identifying the factitious behavior. He gave the example of a patient suspected of having factitious disorder who developed septicemia after her boyfriend proposed marriage. The consultant suggested that the patient might feel a need to punish herself when good things happened to her. She agreed, and soon after, admitted that she had injected a contaminant intravenously (Eisendrath 2001). The second technique is the therapeutic double bind. The physician presents the patient with a new medical intervention to treat his or her illness. The patient is told that one possibility is that the patient’s illness has a factitious origin, and that, if so, the treatment would not be expected to work while, if the illness is biological, the treatment will work and the patient will improve. The patient must decide to give up the factitious illness or admit it. A third technique is to provide the patient with a face-saving way, such as hypnosis or biofeedback, of giving up his or her symptoms without admitting that they are not genuine. Eisendrath (2001) points out that in emergent situations, there may not be time for nonconfrontational techniques, and more directly confrontational means may be necessary.

While many patients with factitious disorder are hesitant to pursue psychiatric treatment, there are numerous case reports of successful treatment of the disorder with long-term psychotherapy. In many of these cases, the therapy lasted several years, though Cohen and Chang (2004) reported a patient with significant improvement after 5 months of treatment (2004). Plassmann (1994b) reports a case series of 24 factitious patients. Twelve of these patients accepted psychotherapy and 10 continued with long-term treatment, lasting up to 4.5 years. He reports “significant, or at least marked, improvement” in those 10 patients. These case reports support the idea that treatment of patients with factitious disorder is not impossible, and these patients can improve. However, expectations must be realistic as improvement in the disorder can take several years (Figure 75–2).

Issues in the Clinician-Patient Relationship
Patients with factitious disorder frequently stir intense countertransference reactions in the health care team. These reactions frequently include anger at having been duped or deceived as well as powerlessness both at the inability to know with certainty the medical reality of the situation and also to definitively treat the patient. These reactions can interfere with compassionate care of the person with factitious disorder, leading to complete dismissal of all of the patient’s complaints and even to punitive retaliation on the
part of the treating team. An important component in the treatment of patients with factitious disorder is the coordination of health care among all providers. This allows for fewer unnecessary interventions, minimizes splitting among the health care team, and allows the health care team to vent and process the strong emotions that arise when caring for factitious patients. It can be helpful to remind ourselves and other members of the treatment team that, while the presenting complaint is factitious, the patient still suffers from a life-threatening illness, and that, despite the havoc these patients can wreak in the treatment setting, they are still usually the greatest victim of their illness.

Special Factors Influencing Treatment

Ethical Considerations
Treating patients with factitious disorder often raises ethical questions regarding confidentiality, privacy, and medical decision-making, and it is important to be alert to these issues. Often, patients with factitious disorder will want to keep their diagnosis confidential, even when to do so may harm the patient or others. For example, although a consulting physician may diagnose a patient with factitious disorder, the patient may refuse consent to reveal this information to the referring physician. If the consultant does inform the referring physician, she has violated the patient’s confidentiality, but if she does not, the referring physician is likely to continue to treat the patient for the incorrect diagnosis. Dilemmas regarding patient privacy also arise with factitious patients. For example, hospital room searches could often help clarify the diagnosis or remove materials the patient is using to harm himself, but these searches also violate the patient’s privacy. Dilemmas surrounding medical decision-making can arise when a patient with factitious disorder refuses treatment or requests potentially harmful treatments. It can often be difficult to resolve these ethical dilemmas. In general, even though the factitious patient is deceptive within the doctor–patient relationship, the physician is not released from his or her responsibilities within that relationship, and the patient retains his or her rights of confidentiality, privacy, and autonomy. As with all the patients, emergency situations require different ethical guidelines. Often, ethics and legal consultations can be very helpful in sorting through the difficult issues of patient care in the setting of factitious disorder.

Factitious Disorder by Proxy
Some individuals pursue the sick role not by feigning illness in themselves, but by creating it in another person, usually someone dependent on the perpetrator. They seek the role of caring for an ill individual (the sick role by proxy). In this disorder, there are two patients, the individual with the diagnosis, and his or her victim. While people who suffer from factitious disorder by proxy have a mental illness, they often also commit criminal acts, usually dependent or child abuse, and the criminal justice and child protective systems are often involved.

Diagnosis

Definition and Diagnostic Features
In factitious disorder by proxy, one person creates or feigns illness in another person, usually a child, though occasionally

the victim is an elder or developmentally delayed adult. The veterinary literature even reports cases of factitious disorder by proxy in which the victim is a pet (Munro and Thrushfield 2001). Factitious disorder by proxy is not defined as a specific disorder in DSM-IV-TR but instead is listed under the “not otherwise specified” heading with research criteria included. The diagnostic criteria for factitious disorder by proxy are similar to that of factitious disorder itself, with the exception of the victim of the feigned or induced illness. While numerous symptoms have been reported, common presentations include apnea, seizures, and gastrointestinal problems. The perpetrators appear extremely caring and attentive when observed, but appear indifferent to the child when they are not aware of being observed (Eisendrath 2001).

Assessment
The diagnosis of factitious disorder by proxy is usually made by having an index of suspicion in a child with unexplained illnesses. Laboratory findings can occasionally confirm the diagnosis, and collateral information from multiple family members can be very useful. In addition, the diagnosis is supported if symptoms occur only in the parent’s presence and resolve with separation. Covert video surveillance has been used to diagnose this condition, though it raises questions of invasion of privacy. In general, it has been felt that the welfare of the child overrides the parent’s right to privacy.

Epidemiology
As in factitious disorder, the exact prevalence of factitious disorder by proxy is unknown. There have been studies of the annual incidence of factitious disorder by proxy in the general population in both the United Kingdom and New Zealand. In New Zealand, the annual incidence of factitious disorder by proxy in children less than 16 years was found to be 2.0/100,000 (18 total cases) (Denny et al. 2001). In the United Kingdom, the annual incidence in children under 16 was 0.5/100,000 (128 total cases) (McClure et al. 1996). As the incidence within clinical populations, an Argentinean survey of 113 children with FUO found four (3.5%) cases of factitious fever (Chantada et al. 1994). A survey of 20,090 children brought in with apnea found 54 (0.27%) to be victims of factitious disorder by proxy (Kravitz and Wilmott 1990). Finally, a review of children brought in for treatment of acute, life threatening episodes of diverse etiologies ranging from seizure disorders to electrolyte abnormalities found 1.5% to be factitious (Rahilly 1991).

Comorbidity Patterns
There is high psychiatric morbidity in the children—many go on to develop factitious disorder or other psychiatric illnesses themselves (McGuire and Feldman 1989). For the adults with factitious by proxy, there is high comorbidity with other psychiatric disorders and a history of abuse. In a review of 451 reported cases of factitious by proxy, Sheridan (2003) found that 23% had another psychiatric disorder, usually depression or a personality disorder; and 22% had a history of abuse. In addition, in reported cases, there is an increased rate (~25–30%) of personal factitious disorder in patients with factitious disorder by proxy (Sheridan 2003, Rosenberg 1987).

Course
Factitious disorder by proxy appears to have a much higher mortality rate than self-inflicted factitious disorder. In Rosenberg’s (1987), survey of 117 victims, there was a 9% mortality rate, and of the 54 victims of the disorder in the apnea survey, three index cases and five siblings were dead at the follow-up (Kravitz and Wilmott 1990). McClure et al. (1996) found that eight of 128 index cases in the UK were fatal (6.25%) while Denny et al. (2001) reported no fatalities in 18 index cases. Sheridan (2003) reviewed 451 reported cases of factitious disorder by proxy and found a 6% mortality rate and 7% rate of long-term or permanent disability. In addition, she found 25% of the known siblings of the victims were known to be dead.

Differential Diagnosis
As with factitious disorder, the differential includes complex medical illness. In addition, in an older child, the differential might include personal factitious disorder in the child. As yet, there are no reports of personal factitious disorder in a child under 8, whereas the victim in factitious by proxy is usually a younger child.

Differences in Developmental, Gender and Cultural Presentations
Boys and girls appear to be victims of factitious disorder by proxy in equal numbers (Rosenberg 1987, Sheridan 2003). However, the perpetrators are usually the mothers. In Rosenberg’s (1987) review of 117 cases, all of the perpetrators were women. In Sheridan’s (2003), subsequent review of 451 cases, 77% of the perpetrators were the birth mothers and 7% were the fathers. The average age of the victim in these two reviews was 49 months (Sheridan 2003) and 40 months (Rosenberg 1987).

Etiology and Pathophysiology
Psychological Factors
As counterintuitive as it is to comprehend why anyone would induce illness in oneself, it can be even more difficult to understand inducing illness in one’s own child. The perpetrator in factitious disorder by proxy appears to seek not the “sick role” but the “parent to the sick child” role. This role is similar to the sick role in that it provides structure, attention from others, caring, and relief from usual responsibilities. In addition, the psychological factors that play a role in other forms of child abuse may also be present.

Social/Environmental Factors
Childhood developmental disturbances are thought to contribute to the development of factitious disorder by proxy. Based on case reports, the perpetrator often has a history of family dysfunction (Bools et al. 1994). In Sheridan’s (2003) review, 22% of perpetrators reported a personal history of either childhood or domestic abuse. In addition, a background in health care was also associated with the disorder: in Rosenberg’s (1987) review, 30% of the perpetrators had a health care background (1987), and in Sheridan’s (2003) review, 14% has a health care background.

Treatment
Due to the high morbidity and mortality, treatment requires at least temporary separation from the parent and
Factitious Disorder by Proxy

A 6-month-old infant presented to the emergency room after a seizure. The family reported no significant past medical history. The infant was resuscitated. There was no evidence of infection, the patient had a normal blood glucose, and the urine toxicology screen was negative. After 5 hours, the child recovered. The infant presented again 5 days later with another seizure. The infant’s blood glucose was low, and continued to fall below normal levels despite administration of dextrose. A blood insulin level was elevated and a c-peptide level suggested endogenous hyperinsulinism. The workup (including CT scan) was otherwise normal. Further history revealed that both grandmothers had Type II diabetes and took oral hypoglycemic agents. A blood test on the infant was positive for sulfonylurea. A case conference was held, and it was discovered that the mother’s first child had been removed from the home due to some charges of abuse. It was recommended that the infant be placed in foster care while the police investigated the case (Owen et al. 2000).

Summary

Patients with factitious disorder seek, often desperately, the sick role. Due to the nature of the disorder, the literature on factitious disorder is largely confined to case reports and case series, limiting the information available. Patients with factitious disorder present with a broad spectrum of signs and symptoms, and effective diagnosis often requires a high index of suspicion. The differential diagnosis of factitious disorder includes physical illness, somatiform disorders, malingering, psychiatric illness, and substance abuse. While factitious disorder is extremely difficult to cure, effective techniques exist to minimize morbidity, and some patients are able to benefit greatly from psychiatric intervention.

References

Dissociative phenomena are best understood through the term désagrégation (disaggregation) originally given by Janet (1920). Events normally experienced as connected to one another on a smooth continuum are isolated from the other mental processes with which they would ordinarily be associated. The dissociative disorders are a disturbance in the organization of identity, memory, perception, or consciousness. When memories are separated from access to consciousness, the disorder is dissociative amnesia. Fragmentation of identity results in dissociative fugue or dissociative identity disorder (DID; formerly multiple personality disorder). Disintegrated perception is characteristic of depersonalization disorder. Dissociation of aspects of consciousness produces acute stress disorder and various dissociative trance and possession states. Numbing and amnesia are diagnostic components of posttraumatic stress disorder (PTSD). These dissociative and related disorders are more a disturbance in the organization or structure of mental contents than in the contents themselves. Memories in dissociative amnesia are not so much distorted or bizarre as they are segregated from one another. The identities lost in dissociative fugue or fragmented in DID are two-dimensional aspects of an overall personality structure. In this sense, patients with DID suffer not from having more than one personality but rather from having less than one personality. The problem involves information processing: the failure of integration of elements rather than the contents of the fragments.

The dissociative disorders have a long history in classical psychopathology, being the foundation on which Freud began his explorations of the unconscious (Breuer and Freud 1955) and Janet (1920) developed his dissociation theory. Although much attention in psychiatry has shifted to diagnosis and treatment of mood, anxiety, and thought disorders, dissociative phenomena are sufficiently persistent and interesting that they have elicited growing attention from both professionals and the public. There are at least four reasons for this:

1. They are fascinating phenomena in and of themselves, involving the loss of or change in identity, or memory, or a feeling of detachment from extreme and traumatic physical events.
2. Dissociative disorders have their genesis in traumatic stress, a phenomena which seems to be ever more present in our society.
3. Dissociative disorders remain an area of psychopathology for which the best treatment is psychotherapy. No pharmacological treatment has been found to effectively treat these disorders, although adjunctive pharmacological interventions can be symptomatically helpful in some cases.
4. Dissociation as a phenomenon has much to teach us about information processing in the brain.

**Development of the Concept**

The French philosopher and psychologist Pierre Janet (1920) is credited with the initial description of the disorder, désagrégation mentale. The French term désagrégation carries with it a different nuance than the English translation, dissociation. It implies a separation of mental contents despite their general tendency to aggregate or be processed together. Janet described hysteria as “a malady of the personal synthesis” (Janet 1920, p 332). The problem is a difficulty in integration rather than a proliferation of components of consciousness, memory, identity, or perception. Janet viewed dissociation as a purely pathological process.
Jean-Martin Charcot (1890), the well-known neurologist and fellow countryman of Janet, was interested in hypnosis and taught the technique to Freud. He believed that even a normal process such as hypnosis, which could be used to access disaggregated mental contents, was itself evidence of dissociative pathology (un état nerveux artificiel ou expérimental, “an artificial or experimental nervous state” [Charcot 1890]). Charcot taught, for example, that once patients were cured of hysteria, they would no longer be hypnotizable. This hypothesis has been proven erroneous. Indeed, many normal individuals are highly hypnotizable and suffer of no psychopathology (Hilgard 1965, Spiegel and Spiegel 2004).

The dissociative disorders might have been studied more intensively during the 20th century had not Janet’s and Charcot’s work been so thoroughly eclipsed by Freud’s psychoanalytic theory, emphasizing as it did repression rather than dissociation. In his early writings with Breuer, Freud explored the unconscious through an examination of similar dissociative phenomena. Cases in the studies on hysteria (Breuer and Freud 1955), such as that of Anna O., clearly involved dissociation. Indeed, Anna O. had many symptoms suggestive of DID. The fragmentation of identity and memory, typical of dissociative states, provided a natural stage for developing a theory involving the unconscious: the processing of information not readily available to conscious awareness. The vehicle they employed to explain this lack of integration was the concept of “hypnoid states.” Breuer and Freud (1955) thought that dissociative symptoms could be attributed to the capacity of certain individuals to enter these hypnoid states, rather than the reverse, as Charcot had thought. To develop a more general theory of human psychopathology, Freud went on to study other kinds of patients, such as those with obsessive-compulsive disorder (Freud 1995) and schizophrenia (Freud 1958a). This shift in the population of patients he studied may well account for his increasing interest in repression rather than dissociation as a model of motivated forgetting. Much has been made of the fact that Freud abandoned the trauma theory of the etiology of the neuroses. What may have happened is that he abandoned the study of individuals for whom trauma could plausibly be applied as an etiological factor in their psychiatric disorder.

Hilgard (1977) developed a neodissociation theory that revived interest in Janet’s psychological principles and dissociative psychopathology. Hilgard postulated divisions in mental structure that were horizontal rather than vertical, as in Freud’s archeological model. The neodissociation model allowed for immediate access to consciousness of any of a variety of warded-off memories, which is not the case in Freud’s system. In the dynamic unconscious model, repressed memories must first go through a process of transformation as they are accessed and lifted from the depths of the unconscious, for example, through the interpretation of dreams or slips of the tongue (Freud 1958b). In Hilgard’s model, amnesia is a crucial mediating mechanism that creates barriers dividing one set of mental contents from another. Thus, flexible use of amnesia is conceptualized as a key defensive strategy. Therefore, reversal of amnesia is an important therapeutic tool.

Repression as a general model for keeping information out of conscious awareness differs from dissociation in four important ways:

1. In repression, information is disguised as well as hidden. Dissociated information is stored in a discrete and untransformed manner, whereas repressed information is usually disguised and fragmented. Even when repressed information becomes available to consciousness, its meaning remains hidden, as is the case of many dream content.

2. Retrieval of repressed information usually requires interpretation and translation. Retrieval of dissociated information can often be direct. Techniques such as hypnosis can be used to access warded-off memories. By contrast, uncovering of repressed information often requires repeated recall trials through intense questioning, psychotherapy, or psychoanalysis with subsequent interpretation (i.e., of dreams).

3. Repressed information is not discretely organized temporally. The information kept out of awareness in dissociation is often for a discrete and sharply delimited time, whereas repressed information may be for a type of encounter or experience scattered across times.

4. Repression is less specifically tied to trauma. Dissociation seems to be elicited as a defense most commonly after episodes of physical trauma, whereas repression is in response to warded-off fears, wishes, and other dynamic conflicts.

Whether dissociation is a subtype of repression or vice versa, both are important methods for managing complex and information charged with negative affect. Given the complexity of human information processing, the synthesis of perception, cognition, and affect is a major task. Mental function is composed of a variety of reasonably autonomous subsystems involving a perception, memory storage and retrieval, intention, and action (Spiegel 1991, Rumelhart and McClelland 1986, Cohen and Servain-Schreiber 1992a, 1992b, Baars 1988). Indeed, a sense of mental unity is an accomplishment, not an automatic consequence of consciousness (Spiegel 1990, Kihlstrom and Hoyt 1990). It is remarkable not that dissociative disorders occur at all, but rather that they do not occur more often.

Models of mental experience are presented in Table 76–1.

Epidemiology

Dissociative disorders are not among the more common psychiatric illnesses but are not rare. Few good epidemiological studies have been performed. Some estimate the prevalence at only 1 per 10,000 in the population (Coons 1984), but far higher proportions are reported among psychiatric populations. In fact, the prevalence of the disorder seems to be associated to the specific population under study. For example, data from the general population suggest that the numbers are higher than initially described by Coons (Kluft 1991). In fact, some have found them to be as high as 1% (Ross 1991, Ross et al. 1991b, Vanderlinden et al. 1991). The data seem to indicate that the incidence may be even higher in some specialized inpatient populations, as high as 3% (Kluft 1991, Ross 1991, Ross et al. 1991a). More

Recent studies (Foote and Smolin 2006) have that 29% of the patients of inner city, hospital-based outpatient psychiatric clinics have received a diagnosis of a dissociative disorder.

More recently, there has been a rise in reported cases of dissociation, which may be better attributed to greater awareness of the diagnosis among mental health professionals. Other factors that may contribute to the apparent increase includes the availability of more specific diagnostic criteria and the fact that some cases may have been previously misdiagnosed as schizophrenia or borderline personality disorder (BPD). Some dissociation experts attribute possible underdiagnosis to family disavowal of sexual and physical abuse. However, there is also controversy about possible overdiagnosis of the syndrome. Yet there are those who propose that the apparent increase is the result of hypnotic suggestion and inadequate handling by therapists (Brenner 1994, 1996, Frankel 1990, Ganaway 1989, 1995, McHugh 1995a, 1995b, Spanos et al. 1985, 1986). They claim that individuals who most commonly have been diagnosed with the disorder are highly hypnotizable and therefore especially sensitive to suggestion or cultural influences. Although psychiatrists’ expectations amplified with hypnotis may account for some cases, they cannot account for many patients diagnosed without benefit of hypnotis or by “skeptical” psychiatrists.

Women make up the majority of cases, accounting for over 90% of the cases, in some studies (Putnam et al. 1986, Coons et al. 1988, Schultz et al. 1989). Researchers (Dominguez et al. 2004) have studied the relationship between exposure to traumatic events, post-traumatic suffering and dissociative symptoms, and the relationship between type of trauma and dissociation in a large sample of outpatient adults seeking treatment at an urban ambulatory mental health clinic in Jerusalem. They found that 83% of subjects reported high levels of intrusion and avoidance symptoms, while 15% reported high levels of dissociative phenomena. These results suggest an association between physical and sexual abuse and high levels of dissociation, particularly in subjects reporting a history of early childhood abuse and an increased prevalence of lifetime traumatic events.

The most commonly diagnosed dissociative disorder diagnosis is the “not otherwise specified” category, both in the US (Mezzich et al. 1989, Saxe et al. 1993) and in non-Western countries. In nondeveloped countries, dissociative trance and possession trance syndromes make the bulk of the cases of dissociative disorder (Adityanjee et al. 1989, Saxena and Prasad 1989). Despite the controversies, dissociative disorders are ubiquitous around the world, although the structure of the symptoms varies across cultures (Adityanjee et al. 1989, Berger et al. 1994, Boe et al. 1993, Brown et al. 1999, Coons and Milstein 1986, Draijer and Langeland 1999, Eriksson and Lundin 1996, Friedl and Draijer 2000, Horen et al. 1995, Modestin et al. 1996, Putnam 1989, Ronquillo 1991, Sar et al. 2000, Wittkower 1970). Not surprisingly, the symptomatology presented seem to reflect cultural norms and biases. For example, in Western cultures, where the importance of the individuality is emphasized dissociation often takes the form of dissociated elements of individual personality. On the contrary, in Eastern cultures where sociocentricity is emphasized, possession trance, in which patients feel themselves to be taken over by an outside entity or entities, is more common.

Te wildt (2004) theorized that the new digital media may adversely impact people’s mental health, an effect that is widely underestimated. Maldonado et al. (2002) conducted a study to compare the effects in society of generic social events. They found that unrelated, consecutive societal events may have an additive effect on the development of trauma-related symptoms and that physical presence at the site of the trauma may not be needed for a person to be psychologically affected. They suggested that distant exposure to vicarious traumatic events (e.g., Internet, television, and media coverage) may somehow sensitize individuals to develop acute stress-like reactions when exposed to future traumatic events.

Diagnostic Criteria and Treatment

Our discussion follows diagnostic criteria for the dissociative disorders as found in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Copyright 2000 American Psychiatric Association.

Dissociative Amnesia

A. The predominant disturbance is one or more episodes of inability to recall important personal information, usually of a traumatic or stressful nature, that is too extensive to be explained by ordinary forgetfulness.

B. The disturbance does not occur exclusively during the course of dissociative identity disorder, dissociative fugue, posttraumatic stress disorder, acute stress disorder, or somatization disorder and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a neurological or other general medical condition (e.g., amnestic disorder due to head trauma).

C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Dissociative Amnesia

Dissociative amnesia represents the classical functional disorder of episodic memory. The disorder does not involve procedural memory or problems in memory storage, as in classic organic amnesia (e.g., Wernicke-Korsakoff syndrome). Furthermore, unlike dementing illnesses, dissociative amnesia is reversible (Janet 1920), for example, by using hypnosis or narcoanalysis. It usually involves one episode, but multiple periods of lost memory have been described (Coons and Milstein 1986). It has three primary characteristics:

1. Type of memory lost: The memory loss is episodic and usually involves the loss of first-person recollection of specific events and identity, rather than knowledge of procedures.

2. Temporal structure: The memory loss is for one or more discrete time periods, ranging from minutes to years. It is not vagueness or inefficient retrieval of memories but rather a dense unavailability of memories that were encoded and stored. Unlike the situation in amnestic disorders, for example, resulting from damage to the medial temporal lobe in surgery (the case of H.M. [Milner 1959]), in Wernicke-Korsakoff syndrome, or in Alzheimer’s-type dementia, there is usually no difficulty in learning new episodic information. Thus, the amnesia of dissociative disorders is typically retrograde rather than anterograde (Loewenstein 1991). However, a dissociative syndrome of continuous difficulty incorporating new information that mimics organic amnestic syndromes has been observed (Schacter 1995).

3. Type of events forgotten: The memory loss is usually for events of a traumatic or stressful nature. This fact has been noted in the language of the DSM-IV diagnostic criteria. In one study (Coons and Milstein 1986), the majority of cases involved child abuse (60%), but disavowed behaviors such as marital problems, sexual activity, suicide attempts, criminal activity, and the death of a relative have also been reported as precipitants.

Dissociative amnesia most frequently occurs after an episode of trauma, and its onset may be gradual or sudden.

Clinical Vignette 1

A 30-year-old woman was beaten and raped by a man who drove her home from a party. She had refused his request to enter her apartment, but he returned a few minutes later claiming that he had to make a phone call. He then sexually assaulted her. She screamed and struggled and called the police immediately afterward. He was arrested when he returned to retrieve some jewelry she had pulled off his neck during the struggle. She had not suffered a concussion but began to lose memory of the rape in the ensuing week. By the end of the week she had no memory of the rape but became listless and depressed. Her psychotherapist used hypnosis to help retrieve her memory, which she was gradually able to do. Her recollections were consistent with her physical injuries and reports of neighbors who heard her screams.

Dissociative amnesia occurs most often in the third and fourth decades of life (Coons and Milstein 1986, Ross 1989, Putnam 1989). Recent studies suggest that the prevalence of dissociative amnesia in the general community is 1.8% (Johnson et al. 2006). Comorbidity with certain Axis I diagnoses, such as conversion disorder, bulimia nervosa, alcohol abuse, and depression are common. On the other hand, Axis II diagnoses of histrionic, dependent, or BPDs occur in a substantial minority of such patients (Coons and Milstein 1986). The typical course of dissociative amnesia is described in Clinical Vignette 2.

Such individuals typically demonstrate not vagueness or spotty memory but rather a complete loss of an episodic memory for a finite period. They may not initially be aware of the memory loss; that is, they do not remember that they do not remember. They often report being told that they have done or said things that they cannot remember.

Some individuals do suffer from episodes of selective amnesia, usually for specific traumatic incidents, which may be interwoven with periods of intact memory. In these cases, the amnesia is for a type of material remembered rather than for a discrete time period (Loewenstein 1991).

Implicit Effects of Dissociated Memories

Although information is kept out of consciousness in dissociative amnesia, it may well exert an influence on conscious behavior: out of sight does not mean out of mind. For example, a rape victim with no conscious recollection of an assault nonetheless behaves like someone who has been sexually victimized. As noted in Clinical Vignette 1, such individuals often suffer detachment and demoralization, may be unable to enjoy intimate relationships, and show hyperarousal to stimuli or circumstances reminiscent of the trauma. This loss of explicit memory with retention of implicit knowledge is similar to priming in memory research. Individuals who have read a word in a list complete a word stem (a partial word such as “pre” for “present”) remember more quickly if they have seen that word minutes or even hours earlier. This priming effect occurs despite the fact that they cannot consciously recall having read the word, or even the list in which it occurred. When asked in a free recall format to list the word they have seen, they cannot name it, yet they act as though they have seen it and do remember it. Similarly, individuals instructed in hypnosis to forget having seen a list of words nonetheless demonstrate priming effects.
of the hypnotically suppressed list (Kihlstrom 1987). It is the essence of dissociative amnesia that material kept out of conscious awareness is nonetheless active and may influence consciousness indirectly (Van Der Hart 2001).

Individuals with dissociative amnesia generally do not suffer disturbances of identity, except to the extent that their identity is influenced by the warded-off memory. It is not uncommon for such individuals to develop depressive symptoms as well, especially when the amnesia occurs in the wake of a traumatic stressor.

**Treatment**
To date, there are no controlled studies that have addressed the treatment of dissociative amnesia. Thus, no proven pharmacological treatments are available (Maldonado et al. 2000).

**Psychotherapy**
Often, patients suffering from dissociative amnesia experience spontaneous recovery when they are removed from the stressful or threatening situation, when they feel safe, and/or when exposed to personal cues from their past (i.e., home, pets, family members) (Kardiner and Spiegel 1947, Loewenstein 1991, Maldonado et al. 2000, Maldonado and Spiegel 2007, Reither and Stoudemire 1988). In cases where exposure to a safe environment is not enough to restore normal memory functioning, pharmacologically facilitated interviews may prove useful (Baron and Nagy 1988, Naples and Hackett 1978, Perry and Jacobs 1982).

**Hypnosis**
Most patients with dissociative disorders are highly hypnotizable on formal testing and are therefore easily able to make use of hypnotic techniques such as age regression (Spiegel and Spiegel 2004). Hypnosis can enable such patients to reorient temporally and therefore achieve access to otherwise dissociated and unavailable memories.

**Abrasion.** If there is traumatic content to the warded-off memory, patients may abreact, that is, express strong emotion as these memories are elicited. Such abractions are rarely damaging in themselves but are not intrinsically therapeutic either. They may be experienced by the patient as a reinflicting of the traumatic stressor. Such patients need psychotherapeutic help in integrating these warded-off memories and the associated affect into consciousness, thereby gaining a sense of mastery over them.

**Screen Technique.** One technique that can help bring such memories into consciousness while modulating the affective response to them is a projective technique known as “the screen technique” (Spiegel 1981). While using hypnosis, such patients are taught to recall the traumatic event as if they were watching it on an imaginary movie or television screen. This technique is often helpful for individuals who are unable to remember the event as if it were occurring in the present, either because for some highly hypnotizable individuals that approach is too emotionally taxing, or in some case, because subjects are not sufficiently hypnotizable to be able to engage in such hypnotic age regression. The screen can be employed to facilitate cognitive restructuring of the traumatic memory, for example, by picturing on the left side of the screen some component of the traumatic experience, and on the right side something they did to protect themselves or someone else during it. This makes the memory both more complex and more bearable.

A particularly useful feature of this technique is that it allows for the recollection of traumatic events without triggering an uncontrolled reliving of the trauma, as is the case of traumatic flashbacks. The screen technique provides a “controlled dissociation” between the psychological and somatic aspects of memory retrieval. Individuals can be put into self-hypnosis and instructed to get their body into a state of floating comfort and safety. They can do this by imagining that they are somewhere safe and comfortable: “Imagine that you are floating in a bath, a lake, a hot tub, or just floating in space.” They are reminded that no matter what they see on the screen their bodies are safe and comfortable: “Do the work on your imaginary screen, not in your body.” In this way the tendency for physiological arousal to accompany and intensify the working through of traumatic memories can be controlled, facilitating the psychotherapeutic work.

The psychotherapy of dissociative amnesia involves accessing the dissociated memories, working through affectively loaded aspects of these memories, and supporting the patient through the process of integrating these memories into consciousness.

**Dissociative Fugue**
Dissociative fugue combines failure of integration of certain aspects of personal memory with loss of customary identity and automatisms of motor behavior (American Psychiatric Association 2000). It involves one or more episodes of sudden, unexpected, purposeful travel away from home, coupled with an inability to recall portions or all of one's past, and a loss of identity or the assumption of a new identity. The onset is usually sudden, and it frequently occurs after a traumatic experience or bereavement. A single episode is not uncommon, and spontaneous remission of symptoms can occur without treatment.

It was originally thought that the assumption of a new identity, as in the classical case of the Reverend Ansel Bourne...

---

**Clinical Vignette 3**

A victim of a violent attempted rape had developed a selective amnesia for much of the physical struggle itself. She had suffered a basilar skull fracture, although she had not been rendered unconscious. She had a generalized seizure shortly after the assault. She initially sought help with hypnosis in an attempt to improve her recollection of the assailant’s face.

She was instructed in the screen technique and used it to relive the assault. She remembered two things she had not previously recalled. One was that she recognized that he intended not merely to rape her but to kill her. On the other side of the screen she came to the realization that the assailant was surprised at how hard she was fighting with him. She became convinced that had she let him drag her into her apartment, she probably would not have survived. She was tearing and frightened as she recalled this aspect of the attack, which had been previously unavailable to consciousness.
She was then instructed to divide the imaginary screen in half, on the left side picturing an image of the viciousness and intensity of the assault on her and on the right side recognizing what she had done to protect herself. She was instructed to concentrate on these two aspects of the assault and then, when she was ready, to bring herself out of the state of self-hypnosis. She was told that she could use this self-hypnosis exercise, several times a day if she wished, as a means of putting her memories of the rape into perspective. This cognitive and emotional restructuring of the traumatic memories made them more bearable in consciousness.

Before hypnosis-facilitated psychotherapy, she had blamed herself for having fought so hard that she was seriously injured. Afterward, she recognized that she may well have saved her life by fighting off the assailant so vigorously. This positive therapeutic outcome occurred despite the fact that she was unable to recall any new details about the assailant's physical appearance. Furthermore, she had brought into consciousness painful and frightening details of the attack involving recognition of the seriousness of the threat to her life. Seeing the seriousness of the danger, however, allowed her to acknowledge the magnitude of the threat and therefore give herself credit for the nature of her response to it.

(James 1984), was typical of dissociative fugue. However, a review of the literature (Reither and Stoudemire 1988) shows that in the majority of cases there is loss of personal identity but no clear assumption of a new identity. Not infrequently, fugue episodes represent dissociated but purposeful activity.

**Treatment**

To date, there are no controlled studies that have addressed the treatment of dissociative fugue. Similarly there are proven pharmacological treatments available (Maldonado et al. 2000). Many cases of dissociative fugue remit spontaneously. Again, hypnosis can be useful in accessing dissociated material. The case in Clinical Vignette 4 was reported by Spiegel and Spiegel (2004).

Hypnosis can be helpful in treating dissociative fugue by accessing otherwise unavailable components of memory and identity. The approach used is similar to that for dissociative amnesia. Hypnotic age regression can be used as the framework for accessing information available at a previous time. Demonstrating to patients that such information can be made available to consciousness enhances their sense of control over this material and facilitates therapeutic working through of emotionally laden aspects of it.

Once reorientation is established and the overt identity and memory loss of the fugue have been resolved, it is important to work through interpersonal or intrapsychic issues that underlie the dissociative defenses. Such individuals are often relatively unaware of their reactions to stress because they can so effectively dissociate them (Spiegel 1974). Thus, effective psychotherapy is anticipatory, helping patients to recognize and modify their tendency to set aside their own feelings in favor of those of others.

Patients with dissociative fugue may be helped with a psychotherapeutic approach that facilitates conscious integration of dissociated memories and motivations for behavior previously experienced as automatic and unwilled. It is often helpful to address current psychosocial stressors, such as marital conflict, with the involved individuals, as in the case of the woman found on the army base. To the extent that current psychosocial stress triggers fugue, resolution of that stress can help resolve it and reduce the likelihood of recurrence. Highly hypnotizable individuals prone to these extreme dissociative symptoms often have great difficulty in asserting their own point of view in a personal relationship (Spiegel and Spiegel 2004, Spiegel 1974, Spiegel et al. 1988). Rather, they interact with others as though they were undergoing a spontaneous trance experience. One such individual described herself as a “disciple in search of a teacher.” Psychotherapy can help such individuals recognize and modify their tendency to unthinking compliance with others and extreme sensitivity to rejection and disapproval.
Clinical Vignette 5

A businessman found himself on a transatlantic flight from California to London without recollecting who he was or how he had gotten on the airplane. In later psychotherapy, exploring these fugue episodes, it was determined that he had had an extremely conflicted relationship with a successful but neglectful father. The father had recently died, leaving him financially well-off but emotionally ambivalent. He had spent his boyhood years in London and he recognized in therapy that the travel to London seemed to represent an unconscious attempt to revisit his childhood years and “set his father straight,” something he had never been able to do while his father was alive. In this case the dissociative fugue was a form of pathological grief reaction.

In the past, medication-facilitated interviews were used to reverse dissociative amnesia or fugue. However, such techniques offer no advantage over hypnosis and are not especially effective (Perry and Jacobs 1982). Not infrequently, the ceremony of injecting the drug elicits spontaneous hypnotic phenomena before the pharmacological effect is felt, and sedation, respiratory depression, and other side effects can be troublesome. It also promotes dependency on the therapist. On the contrary, when hypnosis is used, patients are trained on self-hypnotic techniques, promoting the use of hypnosis instead of spontaneous dissociation. This enhances the patients’ level of control while enhancing a sense of mastery and self-control.

Clinical Vignette 6

A woman in a Veterans Administration hospital had lost all memory for the preceding 10 months and insisted that she was in another hospital where she had been the previous December. She proved on testing with the hypnotic induction profile (HIP; Spiegel and Spiegel 2004) to be highly hypnotizable (10 of 10 on the induction score). She was hypnotized with a simple rapid induction technique involving the following instruction: “On one, do one thing, look up. On two, do two things, slowly close your eyes and take a deep breath. On three, do three things, let the breath out, let your eyes relax but keep them closed, and let your body float. Then let one hand or the other float up into the air like a balloon and that is your signal to yourself that you are ready to concentrate.”

When she did this, she was told that we would be changing times, counting backward in years, and that when her eyes opened she would be at an earlier time in her life. We agreed that when I touched her forehead, she would close her eyes and we would change times again. We then began counting several years back. When she opened her eyes, she spoke as though she were in a different location earlier in her life. She was reoriented to the time when she really was in the other psychiatric hospital in a different city, and she talked about that experience. She was then instructed to close her eyes again and count forward in months to the present month. She opened her eyes and was then properly oriented and had episodic memory for what had transpired in her life in recent months.

Depersonalization Disorder

This dissociative disorder involves lack of integration of one or more components of perception. The essential feature of depersonalization disorder is the occurrence of persistent feelings of unreality, detachment, or estrangement from oneself or one’s body, usually with the feeling that one is an outside observer of one’s own mental processes (American Psychiatric Association 2000, Steinberg 1991). Individuals suffering depersonalization are distressed by it. They are aware of some distortion in their perceptual experience, and are not technically hallucinating or psychotic. Affected individuals often fear that they are “going crazy.” The symptom is not infrequently transient. A recent study of community adults suggests the prevalence of depersonalization disorder is 0.8% (Johnson et al. 2006).

Derealization (i.e., an altered perception of their surroundings resulting in the world seeming unreal or dream like) occurs frequently in patients with depersonalization disorder. Such individuals often ruminate anxiously about this symptom and are preoccupied with their own somatic and mental functioning.

The symptom of depersonalization frequently co-occurs in a variety of other psychiatric disorders, such as in patients with anxiety disorders (e.g., panic, phobia). Depersonalization may be seen as a symptom of PTSD, and may also be present as a symptom of alcohol and drug abuse or withdrawal, a side effect of prescription medications, during periods of stress, and it may be elicited by sensory deprivation. The symptom of depersonalization is also commonly seen in the course of a number of other neurological and psychiatric disorders (Pies 1991). It is considered a disorder when it is a persistent and predominant symptom. The phenomenology of the disorder involves both the initial symptoms themselves and the reactive anxiety caused by them.

Treatment

To date, there are no controlled studies (using either psychotherapy or pharmacological agents) that have demonstrated their usefulness in the treatment of depersonalization (Maldonado et al. 2000). Nevertheless, we know that depersonalization is most often transient and may remit without formal treatment. Recurrent or persistent depersonalization should be thought of both as a symptom in itself and as a component of other syndromes requiring treatment, such as anxiety disorders and schizophrenia.

The symptom of depersonalization may respond to training in self-hypnosis. Sometimes, a hypnotic induction by itself or the deliberate worsening of symptoms by the therapist may be used as a method to teach patients how to control these episodes. For example, a hypnotic induction may be used to induce transient depersonalization symptoms, such as a sense of detachment from part of the body. This is a useful exercise, in that by having a structure for inducing the symptoms, one provides the patient with a context for understanding and controlling them. Patients may be instructed on how these episodes, usually experienced by them as spontaneous and erratic, are similar to a form of hypnotic dissociation that can be modified and eventually controlled. Such individuals can be taught to induce a pleasant sense of floating lightness or heaviness in place of the anxiety-related somatic detachment. The use of an imaginary screen to picture problems in a
Dissociative Identity Disorder

A 54-year-old businesswoman was referred for evaluation of lifelong depersonalization symptoms, episodes characterized by a feeling of detachment, alternating with eruptions of uncharacteristic anger, or childlike behavior. The episodes occurred more frequently after relationship problems or losses, dismissive or controlling treatment by others, and especially around important family holidays, such as Thanksgiving and her birthday. She had a history of parental physical abuse early in life. She was tested with the Hypnotic Induction Profile and scored 8.5/10 points, indicating moderate-to-high hypnotizability. She was taught a self-hypnosis exercise in which she felt her body to be floating comfortably while she pictured herself in a pleasant outdoor scene. She was then able to experience an emotion of anger as she thought about her last episode of depersonalization, and made an association to an earlier episode of parental mistreatment. She was instructed to practice this self-hypnosis exercise three times a day, and observe if she felt a depersonalization episode coming on. Follow-up 3 weeks later indicated that there was a decrease in the number of spontaneous depersonalization episodes, and she found that she could use the self-hypnosis to identify and work through feelings that she had previously been unaware of or that had created difficulties for her. She was, for example, able to recognize a feeling of hurt and rejection at the close of a prior therapy, cry over it, and “move beyond” it. She saw the hypnosis exercise as a means of understanding previously alien feelings and working through them, while increasing her ability to induce relaxation and handle stress.

way that detaches them from the typical somatic response is also helpful (Spiegel and Spiegel 2004). Other relaxation techniques such as systematic desensitization, progressive muscle relaxation, and biofeedback may also be of help. Psychotherapy aimed at working through emotional responses to any traumatic or other stressors that tend to elicit depersonalization may also be helpful.

Given the absence of proven pharmacological approaches, the trier must balance the potential therapeutic benefit and risk of any regimen used. Antianxiety medications are most commonly used and may be helpful in reducing the amplification of depersonalization caused by anxiety. However, because antianxiety drugs can themselves produce symptoms of depersonalization and derealization their use should be carefully monitored. Increasing dosage, a standard technique when there is lack of therapeutic response, may also increase symptom intensity, leading to a spiral of increasing symptoms and drug dosage but without therapeutic benefit. Appropriate pharmacological treatment for comorbid disorders is an important part of treatment. Consider the use of antianxiety medications for generalized anxiety or phobic disorders (Stein and Uhde 1989) or of antipsychotic medications (Nuller 1982) for psychotic disorders is often beneficial in conditions in which there is contributory comorbidity.

Dissociative Identity Disorder

(DID) is the most popular, widely discussed, and recognized of the dissociative disorders. By definition, the disorder involves the “presence of two or more distinct identities or personality states each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self.” These identities or personality states recurrently take control of the person’s behavior” (American Psychiatric Association 2000). Often amnesia is present:

### DSM-IV-TR Criteria 300.14

**Dissociative Identity Disorder**

A. The presence of two or more distinct identities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self).

B. At least two of these identities or personality states recurrently take control of the person’s behavior.

C. Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness.

D. The disturbance is not due to the direct physiological effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or a general medical condition (e.g., complex partial seizures).

**Note:** In children, the symptoms are not attributable to imaginary playmates or other fantasy play.
There are no definitive studies confirming the absolute prevalence of DID, although there is widespread agreement that the number of diagnosed cases has increased considerably in the US and some European countries in the past two decades (Boon and Draijer 1993). Several studies have estimated the prevalence as approximately 1% of psychiatric inpatients (Saxe et al. 1993, Ross et al. 1991a). On the other hand, recent studies (Foote et al. 2006) suggest the incidence in a mental health clinic population may be as high as 5%. There are several factors that may account for the apparent increase in the number of reported cases including: (1) a more general awareness of the diagnosis among mental health professionals. (2) the availability of specific diagnostic criteria. (3) reduced incidence of misdiagnosis of DID patients as having other disorders with similar presentation (e.g., psychosis, BPD).

Some authors have attributed the increase in reported cases to a multitude of artificial factors including: social contagion, the result of hypnotic suggestion, and misdiagnosis (Frankel 1990, Ganaway 1995, McHugh 1995a, 1995b, Spanos et al. 1986). They argue that patients diagnosed with DID are highly hypnotizable, thus by definition quite suggestible and therefore especially vulnerable to direct or implicit hypnotic suggestion by overzealous therapists. They have noted that not infrequently a few specialist psychiatrists make the vast majority of diagnoses.

Counter to their arguments, the data suggest that the symptoms of patients diagnosed by specialists in dissociation do not differ from those of patients diagnosed by psychiatrists, psychologists, and physicians in more general practice who diagnose one or two cases a year. Also, DID patients have been noted to persist in presenting symptoms for an average of 6.5 years before acquiring the diagnosis (Putnam 1985). Similarly, they often encounter many psychiatrists and psychologists who are convinced that they do not have DID, but instead another disorder, such as schizophrenia. It is indeed true that these patients are highly hypnotizable and therefore suggestible (Spiegel 1974, Frischholz 1985). If the symptoms were to be created by suggestibility alone, it seems likely that they would accept a suggestion that they have some other disorders as well (e.g., schizophrenia or BPD). Because of this, care must be taken in the manner in which the illness is presented to them. However, it is unlikely that the increased number of cases currently reported is accounted for by suggestion alone. Reduction in previous misdiagnosis and increased recognition of the prevalence and sequelae of physical and sexual abuse in childhood (Kluft 1984a, 1991, Frischholz 1985, Spiegel 1984, Terr 1991, Herman et al. 1989) are also reasonable explanations.

Course

The disorder may present in childhood, but more typically is recognized between adolescence and the third decade of life (Kluft 1984a). The symptoms rarely emerge after the age of 40 years. Nevertheless, there is often considerable delay between initial symptom presentation and diagnosis (Putnam et al. 1986). When the condition goes untreated, DID is a chronic and recurrent disorder. Available data suggest it rarely remits spontaneously.

Even after they begin to be manifested, the symptoms may not be evident for a certain period of time (Kluft 1985). Some have called DID “a disease of hiddenness” (Schacter 1995). The dissociation itself makes it difficult for the patients to effectively self-monitor and to accurately report their symptoms or the personal history that may trigger a suspicion of the diagnosis. Most patients suffering from DID are not fully aware of the extent of their dissociative symptomology. When they do, they are usually reluctant to bring up symptoms because of confusion or shame about the illness or because of having experienced skepticism from mental health professionals in the past. Similarly, the shame associated with previous victimization and fear of retribution may also inhibit reporting of symptoms.

Comorbidity

The most significant comorbid psychiatric conditions include depression, substance abuse, and BPD (Maldonado and Spiegel 2005). Sexual dysfunction, eating, and sleep disorders occur less frequently. Self-mutilative behavior, impulsivity, and labile interpersonal relationships are frequently exhibited by DID patients. In fact, nearly one-third of DID patients also meet diagnostic criteria for BPD. Patient exhibiting this interaction (i.e., DID plus BPD) also experience higher levels of depression (Horevitz and Braun 1984).

There may be a common etiological pathway to both DID and BPD. In fact, research shows a high incidence of dissociative symptomatology in many patients with BPD, especially those who report histories of physical and sexual abuse (Chu and Dill 1990, Ogata et al. 1990). By the same token, many DID and BPD patients also exhibit symptoms consistent with the diagnosis of PTSD (e.g., intrusive

Not only is the number of comorbid psychiatric problems lengthy, but also DID patients face the problem of misdiagnosis. As mentioned before, sometimes DID patients are misdiagnosed as having schizophrenia or some other psychotic disorder (Kluft 1987). The likely source of the misdiagnosis is the misinterpretation of the patient’s report of having more than one person living inside them as a bizarre delusion rather than evidence of dissociation. Also, DID patients may report experiencing auditory hallucinations when one personality state speaks to or comments on the activities of another. DID patients may also be diagnosed as having conversion disorder (Ross et al. 1990) or some other somatoform disorder given the preponderance of psychosomatic complaints, such as migraine headaches and other ailments (Spiegel 1987). Practitioners must bear in mind that some studies have identified that approximately a third of DID patients may suffer from complex partial seizures (Schenk and Bear 1981). Therefore, newly diagnosed cases with DID should be evaluated for the possibility of a seizure disorder or some other medical conditions.

**Psychological Testing**
At least three objective measures may help in the diagnosis of DID cases. First, DID patients score far higher than normal individuals on standard measures of hypnotizability, whereas psychotic patients tend to have lower than normal scores or the absence of high hypnotizability (Spiegel et al. 1982, Spiegel and Fink 1979, Lavoie and Sabourin 1980, Pettinati 1982, Pettinati et al. 1990, Van Der Hart and Spiegel 1993). Second DID patients score extremely high on scales of trait dissociation, (Bernstein and Putnam 1986, Ross 1989, Carlson et al. 1993). In contrast to normal populations and other groups of patients (Ross et al. 1990, Steinberg et al. 1990). Third, form level on the Rorschach test is usually within the normal range in DID patients, but there are frequent emotionally dramatic responses, often involving mutilation of a type that is often seen in histrionic personality disorder (Scroppo et al. 1998). Good form level is also useful in distinguishing patients with DID from those with schizophrenia, who have poor form level.

**Treatment**

*Psychotherapy*

**Therapeutic Direction.** DID patients may be aided in gaining control over the dissociative process underlying their symptoms in a number of ways (Maldonado et al. 2000, Maldonado and Spiegel 2007). The psychotherapy of DID should involve a form of structured empathy in which patients experiencing themselves as damaged and fragmented is acknowledged, while the therapist helps patients understand that the fundamental problem was a failure of integration of disparate memories and aspects of the self. Viewed in this way, DID patients suffer from having less than one personality rather than more than one. The ultimate goal in the therapy of DID is to facilitate integration of disparate elements. This can be done in a variety of ways.

Clear limit setting and commitment on the part of the therapist to help all portions of the patient’s personality structure learn about warded-off information is paramount. Given the nature of the genesis, secrets are frequently a problem with DID patients. Often, patients use their therapists to reinforce a dissociative strategy of withholding relevant information from certain personality states. Therefore, it is imperative that therapists clarify explicitly that they will not reinstate the preponderance of psychosomatic symptoms, such as migraine headaches and other ailments (Spiegel 1987). Practitioners must bear in mind that some studies have identified that approximately a third of DID patients may suffer from complex partial seizures (Schenk and Bear 1981). Therefore, newly diagnosed cases with DID should be evaluated for the possibility of a seizure disorder or some other medical conditions.

**Hypnosis**

Hypnosis can be helpful in facilitating psychotherapy as well as establishing the diagnosis of DID (Spiegel and Spiegel 2004, Braun 1984, Kluft 1982, Maldonado et al. 2000). Hypnosis may be helpful in a variety of ways. First, mere structure of hypnotic induction may elicit dissociative phenomena. Second, hypnosis may help facilitate access to dissociated personalities. Dissociation may occur spontaneously during hypnotic induction, but it may be elicited formally by using a variety of therapeutic techniques, such as age regression, to reorient to a time when a different personality state was manifest. The process of hypnosis-mediated dissociation may become the means of teaching DID patients how to control the dissociative process. Third, entering the state of hypnosis may make it possible simply to address and elicit different identities or personality states at the therapist’s suggestion. After some formal exercises such as this, it is often possible to ask the patient to speak with a given alter personality, without the formal use of hypnosis.
Stages of Therapy. Because the loss of memory in DID is complex and chronic (Charcot 1890), its retrieval is likewise a more extended and integral part of the psychotherapeutic process. The therapy becomes an integrating experience of information sharing among disparate personality elements. By thinking of DID as a chronic form of PTSD, the focus of psychotherapy is concentrated on working through traumatic memories in addition to controlling the dissociation. The controlled access to dissociated memories greatly facilitates the process of psychotherapy. As discussed before (e.g., dissociative amnesia) a variety of strategies can be employed to help patients with DID break down amnesic barriers. Once memories of earlier traumatic experience have been brought into consciousness, it is crucial to help the patient work through the painful affect, inappropriate self-blame, and other reactions to these memories (Lindemann 1944, Spiegel et al. 1982). This therapeutic process can be thought of as a kind of grief work (Lindemann 1944) in which information retrieved from memory is reviewed, traumatic memories are put into perspective, and emotional expression is encouraged and worked through. This process makes it possible for patients to endure and helps them disseminate the information as widely as possible among various parts of the patient’s personality structure. Instructions to other alter personalities to “listen” while a given one is talking and reviewing previously dissociated material can be helpful.

Projective techniques (e.g., screen technique) may help make the traumatic memories more bearable by placing them in a broader perspective, one in which trauma victims can also identify adaptive aspects of their response to the trauma. This approach may help DID patients work through traumatic memories, enabling patients to consciously bear the content of these recollections and reducing the need for dissociation as a means of keeping such memories and associated painful affect out of consciousness.

The Rule of Thirds. The rule of thirds (Kluft 1991, Schacter 1995) may help therapists pace the course of a treatment that otherwise can be emotionally taxing and time consuming. Kluft suggests that therapists spend the first-third of the psychotherapy session assessing the patient’s current mental state and life problems. Carefully defining a problem area that might benefit from retrieval into conscious memory and working through. Then, therapists should spend the second-third of the session accessing and working through this memory. Finally, the last-third is used helping patients assimilate the information, regulate and modulate emotional responses, and discuss any responses to the therapist and plans for the immediate future. Appropriate limits must be set concerning self-destructive or threatening behavior, agreements must be made regarding physical safety and treatment compliance, and other matters must be presented to the patient in such a way that dissociative ignorance is not an acceptable explanation for failure to live up to the agreements.

Integration. The ultimate goal in the psychotherapy of DID is integration of the patient’s multiple ego states. Therapists must be aware that often one or more of the personality states may exert considerable resistance to the process of integration, particularly early in the process of therapy. The reason for this resistance is the patient’s fear that attempts at integration are part of the therapist plan to “eliminate” or “kill” personalities. These fears must be worked through the course of therapy and the patient needs to understand that the goal is to learn how to control the episodes of dissociation leading eventually to full integration of all parts, rather than the elimination of any. Done this way, patients develop a sense of gradually being able to control their dissociative processes in order to work through the traumatic memories. In order to enhance mastery and control, the process of the psychotherapy must help patients minimize rather than reinforce the content of traumatic memories, which often involves re-experiencing a sense of helplessness in a symbolic re-enactment of the trauma (Freud 1958a, Maldonado et al. 2000). Although there have been no controlled trials of the outcome of psychotherapy for this disorder, case series reports indicate a positive outcome in a majority of cases (Kluft 1984b, 1986, 1991). The stages of therapy are presented in Table 76–2.

Traumatic Transference

Transference applies with special meaning to patients who have been physically and sexually abused, especially in childhood. These patients have experienced individuals who are presumed to be caretakers acting instead in an exploitative and sometimes sadistic fashion. Although their reality testing is good enough that they can perceive genuine caring, they often unconsciously expect psychiatrists to exploit them. They may experience the process of working through of traumatic memories as a reinforcing of the trauma, and perceive the psychiatrist as taking sadistic pleasure in their suffering. Sometimes, patients may misattribute the passivity on the part of the psychiatrist with some uncaring family figure who knew that abuse was occurring but did little or nothing to stop it. It is important in managing the therapy of trauma victims to keep these issues in mind and make them frequent topics of discussion. This can diffuse, if not eliminate, such traumatic transference distortions of the therapeutic relationship (Spiegel 1988).
Psychopharmacology

As with other dissociative disorders, there is little evidence that psychoactive drugs are of great help in reversing dissociative symptoms (Maldonado et al. 2000). In the past, short-acting barbiturates such as sodium amobarbital were used intravenously to reverse functional amnesia, but this technique is no longer employed, largely because of poor results (Perry and Jacobs 1982). Research data provide no evidence suggesting that any medication regimen has any significant therapeutic effect on the dissociative process manifested by DID patients (Loewenstein 1991, Markowitz and Gill 1996, Putnam 1989). To date, pharmacological treatment has been limited to symptom control (e.g., insomnia, panic attacks) or the management of comorbid conditions (e.g., depression).

Of all available classes of psychotropic agents, antidepressants are the most useful class for the treatment of patients with DID. That is because patients suffering from dissociation frequently experience comorbid dysthymic or major depressive disorder. Nevertheless, medication compliance may be a problem with dissociative patients because dissociated personality states may interfere with medication taking or may take excess medication in an overdose attempt. Because of this the newer agents—selective serotonin reuptake inhibitors (SSRIs)—are particularly useful, given their high level of effectiveness, lower side effect profile, and even lower danger in overdose, compared with tricyclic antidepressants and monoamine oxidase inhibitors.

Benzodiazepines have mostly been used to facilitate recall by controlling secondary anxiety associated with retrieval of traumatic memories (i.e., medication-facilitated interviews). All CNS-depressant agents may cause sudden mental state transitions, which may in turn increase rather than decrease amnesic barriers. Therefore, as useful as they could be on short-term basis (i.e., acute management of a panic attack), the long term of these agents may, in fact, contribute rather than treat dissociative episodes. Thus, the long-term use of these agents is not indicated.

Anticonvulsant agents may be useful in this patient population. As we discussed earlier, seizure disorders have a high rate of comorbidity with DID. As expected, anticonvulsant agents may help control the dissociation associated with epileptogenic activity. We also know that anticonvulsant agents have proven effective in the management of mood disorders that are prevalent in DID patients. Similarly, anticonvulsant agents have been found to be effective in the treatment of impulsive behaviors associated with personality disorders and brain injury. These agents may produce less amnestic side effects than the benzodiazepines and thus may be preferred in the treatment of certain psychiatric conditions such as impulse control and anxiety states. Due to potential problems such as neurological side effects, blood dyscrasias, and hepatotoxicity there is greater need for closer monitoring, making their use less desirable than the newer SSRIs.

Of all pharmacological agents available, antipsychotics may be the the least desirable. There is no evidence that they are useful in reducing dissociative symptoms. In fact, there have been reports of increased levels of dissociation and an increased incidence of side effects when used in patients suffering from dissociative disorders. Therefore, the use of these agents in DID is not recommended.

Dissociative Trance Disorder

Dissociative Trance

Dissociative trance disorder has been divided into two broad categories, dissociative trance and possession trance (American Psychiatric Association 2000). Dissociative trance phenomena are characterized by a sudden alteration in consciousness, not accompanied by distinct alternative

DSM-IV-TR Criteria

Dissociative Trance Disorder

A. Either (1) or (2):

(1) trance, i.e., temporary marked alteration in the state of consciousness or loss of customary sense of personal identity without replacement by an alternate identity, associated with at least one of the following:
   (a) narrowing of awareness of immediate surroundings, or unusually narrow and selective focusing on environmental stimuli
   (b) stereotyped behaviors or movements that are experienced as being beyond one’s control

(2) possession trance, a single or episodic alteration in the state of consciousness characterized by the replacement of customary sense of personal identity by a new identity. This is attributed to the influence of a spirit, power, deity, or other person, as evidenced by one (or more) of the following:
   (a) stereotyped and culturally determined behaviors or movements that are experienced as being controlled by the possessing agent
   (b) full or partial amnesia for the event

B. The trance or possession trance state is not accepted as a normal part of a collective cultural or religious practice.

C. The trance or possession trance state causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The trance or possession trance state does not occur exclusively during the course of a psychotic disorder (including mood disorder with psychotic features and brief psychotic disorder) or dissociative identity disorder, and is not due to the direct physiological effects of a substance or a general medical condition.

identities. In this form the dissociative symptom involves an alteration in consciousness rather than identity. Also, in dissociative trance, the activities performed are rather simple, usually involving sudden collapse, immobilization, dizziness, shrieking, screaming, or crying. Memory is rarely affected, and if there is amnesia, it is fragmented.

Dissociative trance phenomena frequently involve sudden, extreme changes in sensory and motor control. A classic example is the ataque de nervios, prevalent in Latin American countries. For example, this phenomenon is estimated to have a 12% lifetime prevalence rate in Puerto Rico (Lewis-Fernandez 1994). A typical episode involves a sudden feeling of anxiety, followed by total body shakes, which may mimic convulsions. This is then followed by hyperventilation, unintelligible screaming, agitation, and often violent bodily movements. Usually, this is followed by collapse and probably transient loss of consciousness. After the episode is over, subjects complain of fatigue and having been confused, although this behavior is dramatically different from classic postictal states. Some subjects may experience amnesia at least to some aspects of the event (Lewis-Fernandez 1994).

Other examples include lata and “falling out.” Lata represents the Malay version of trance disorder. In these episodes, afflicted individuals usually experience a sudden vision, mostly of a threatening spirit. The observable behavior includes screaming or crying and physical manifestation of overtly violent behavior, which often requires the sufferer to be physically restrained. Patients often report episodes of amnesia, but there is no clear possession by the offending spirit (Lewis-Fernandez 1994). On the other hand, “falling out” more commonly occurs among African-Americans in the southern US. Similarly to other trance episodes, the affected individual may enter a trance state, followed by bodily collapse, the inability to see or speak, despite the fact that they are fully conscious. Temporary confusion may be observed, although subjects are not usually amnesic to what occurred during the episode (Lewis-Fernandez 1994).

Possession Trance
In contrast to dissociative trance episodes, possession trance involves the assumption of a distinct alternative identity. The new identity is presumed to be that of a deity, ancestor, or spirit who has transiently taken possession of the subject’s mind and body. Different from dissociative trance episodes, which are characterized by rather crude, simplistic, regressive-like behaviors, possession trance victims often exhibit rather complex behavior. During these episodes, subjects may, for example, express otherwise forbidden thoughts or needs, engage in unusually and uncharacteristic aggressive behavior (e.g., verbal or physical expressions of aggression), or may attempt to negotiate for change in family or social status. Also, in contrast to dissociative trance episodes, possession trance episodes often are followed by dense amnesia for a large portion of the episode during which the spirit identity was in control of the subject’s behavior.

Cultural Context
Dissociative-like phenomena have been described in virtually every culture (Lewis-Fernandez 1994, Katz 1982, Kirmayer 1994). Yet they appear to be more prevalent in the less heavily industrialized Second and Third World countries. Studies on the prevalence of dissociative disorders in India have suggested that the 1-year prevalence of dissociative trance disorder is approximately 3.5% of all psychiatric hospitalizations, making it a highly frequent mental disorder (Adityanjanee et al. 1989, Saxena and Prasad 1989). Trance and possession syndromes are by far the most common type of dissociative disorders seen around the world. On the other hand, DID, which is relatively more common in the US, is virtually never diagnosed in underdeveloped countries. This difference in prevalence and distribution of dissociative disorder across different populations may be mediated by cultural, as well as biological factors. For example, Eastern culture is far more sociocentric than Western culture. Thus, being “possessed” by an outside entity would be more culturally comprehensible and acceptable in the East. On the other hand, an apparent proliferation of individual identities would fit better with the Western preoccupation with individualism. Nonetheless, the underlying dissociative mechanism inhibiting integration of perception, memory, and identity may suggest a common underlying mechanism amongst these dissociative syndromes.

Trance and possession episodes are usually understood as an idiom of distress and yet they are not viewed as normal. That is, they are not a generally accepted part of cultural and religious practice, which often does involve normal trance phenomena, such as trance dancing in the Balinese Hindu culture. Trance dancers enjoy the remarkable privilege of being the only portion of this socially rigid society able to elevate their social status. The way they are able to do that is by developing the ability to enter trance states. During these altered states of consciousness, which usually occur within the context of a socially acceptable ceremony setting, they dance over hot coals, hold a sword at their throat, or in other ways exhibit supernormal powers of concentration and physical prowess. The mechanism mediating these phenomena is not fully understood, but there is evidence of elevations in plasma noradrenaline, dopamine, and beta-endorphin among Balinese trance dancers during trance states. This form of trance is considered socially normal and even exalted.

By contrast, disordered trance and possession trance are viewed by the local community as an aberrant form of behavior that requires intervention. Such symptoms often arise in the context of family or social distress, for example, discomfort in a new family environment. Thus, cultural informants make it clear that people with dissociative trance disorder are abnormal.

Differences in culture clearly influence almost all mental disorders (Table 76–3). Delusional content of a schizophrenic patient is often dramatically different in a Hindu versus a Christian. Similarly, the manifestations of major depressive disorder may take a different form in China, where it looks more like what used to be called neurasthenia, where it may present with far more somatic symptoms, compared with predominantly guilty ruminations, seen in Western patients (Kleinman 1977). Similarly, variations in the form and presentation of the various dissociative disorders, depending on the population under study, only underscore the ubiquity of the mechanism of dissociation. The DSM-IV task force voted to include dissociative trance disorder in the appendix of the DSM-IV (American Psychiatric Association 2000) to stimulate further research on the question of whether it should be a separate Axis I disorder or whether it should
be included as a subtype in the category of dissociative disorders not otherwise specified.

**Treatment**

Treatment of these disorders varies from culture to culture. Rubbing the body with special potions, negotiating to change the affected person’s social circumstances, and physical restraint are often used. Ceremonies to remove or appease the invading spirit are also employed.

**Dissociation and Trauma**

One of the important developments in the modern understanding of dissociative disorders is the establishment of a clearer link between trauma and dissociation (Spiegel and Cardena 1991, 1994). Although the role of traumatic stress in eliciting dissociative symptoms was a part of Janet’s early thinking (Van Der Hart et al. 1989) as well as that of Breuer and Freud (1955), more attention was paid to the symptoms, developmental issues, and personality features than to the role of traumatic stressors themselves. Later work has examined in more detail the proximate role of trauma in eliciting dissociative symptoms.

Trauma can be understood as the experience of being made into an object, a thing, the victim of someone else’s rage or of nature’s indifference. Trauma represents the ultimate experience of helplessness: loss of control over one’s own body. There is growing clinical evidence that dissociation occurs as a defense during traumatic experiences, constituting an attempt to maintain mental control at the moment when physical control has been lost (Spiegel et al. 1988, Putnam 1985, Kluft 1984, Spiegel 1984). Many assault victims report floating above their body, feeling sorry for the person being assaulted beneath them. Patients, victims of childhood abuse, have reported “taking themselves elsewhere” where they could “safely play,” by themselves or with imaginary friends, while their bodies were brutally abused by a perpetrator. In fact, there is evidence (Terr 1991) that children exposed to multiple traumas as opposed to single-blow traumas are more likely to use dissociative defense mechanisms, which include spontaneous trance episodes and amnesia.

As noted in the section on DID, there is an accumulating literature suggesting a connection between a history of childhood physical and sexual abuse and the development of dissociative symptoms (Coons and Milstein 1986, Kluft 1984a, 1985, Spiegel 1984). Similarly, dissociative symptoms have been found to be more prevalent in patients with Axis II disorders, such as BPD, when there has been a history of childhood abuse (Herman et al. 1989, Chu and Dill 1990).

Another means of examining the putative connection between dissociation and trauma is to look at the prevalence of dissociative symptoms after recent trauma (Spiegel and Cardena 1991). If it is indeed the case that trauma seems to elicit dissociative symptoms, they should be observable in the immediate aftermath of trauma. In the early literature examining responses to trauma, Lindemann (1944), studying the aftermath of the Coconut Grove fire, observed that the individuals who acted as though little or nothing had happened had an extremely poor long-term prognosis. These were individuals who had been injured or had lost loved ones. Indeed, it was the absence of post-traumatic symptoms in this group, compared with the agitation, dysphoria, and restlessness that typified the majority of survivors, that led him to formulate the normal process of acute grief.

Several subsequent researchers have observed that psychic numbing is a predictor of later PTSD symptoms. In fact, Solomon and Mikulincer (1988) observed that psychic numbing accounted for 20% of the variance in later PTSD symptoms among Israeli combat soldiers. Similarly, McFarlane (1986) found that numbing in response to the Ash Wednesday bush fires in Australia was a strong predictor of later post-traumatic symptoms.

Research on survivors of other life-threatening events, including hostage taking, indicated that more than half have experienced a sense of detachment, feelings of unreality (i.e., depersonalization), lack of emotions, hyperalertness, and automatic movements (Noyes and Kletti 1977, Madakasira and O’Brien 1987, Sloan 1988, Noyes and Slymen 1978–1979). Numbing, anhedonia, and an inability to feel deeply about anything were reported in about a third of the survivors of the Hyatt Regency skywalk collapse (Wilkinson 1983) and in a similar proportion of survivors of the North Sea oil rig disaster (Holen 1993). These findings are consistent with our studies of survivors of the Loma Prieta earthquake (Cardena and Spiegel 1993). One-quarter of this sample of normal students reported marked depersonalization during and immediately after the event.

Although these dissociative responses to traumatic stressors have been conceptualized as adaptive defenses to overwhelming situations, the thrust of the literature indicates that the presence of dissociative symptoms in the immediate aftermath of trauma is a strong predictor of the development of later PTSD (Solomon and Mikulincer 1988, McFarlane 1986, Freinkel et al. 1994, Koopman et al. 1994, Marmar et al. 1994, Birnes 2001). For example, victims of the Oakland-Berkeley firestorm who reported significant dissociative symptoms had suffered relatively greater exposure to the fire and also were more likely to have significant symptoms.

of PTSD 7 months later (Koopman et al. 1994). Similarly, Marmar et al. (1994) found that peritraumatic dissociation was a strong predictor of later PTSD symptoms among Vietnam veterans. Thus, physical trauma seems to elicit dissociation, perhaps in individuals who are prone to the use of this defense by virtue of either previous traumatic experience or a constitutional tendency to dissociate. This dissociative reaction may, in some cases, resolve quickly. However, in others it may become the matrix for later posttraumatic symptoms, such as dissociative amnesia for the traumatic episode. Indeed, more extreme dissociative disorders, such as DID, have been conceptualized as chronic forms of PTSD episode. Therefore, dissociation occurrence at the time of the trauma are strongly predictive of later development of PTSD of the trauma tends to have an off-on quality involving either intrusion or avoidance (Horowitz 1976), in which victims either intensively relive the trauma as though it were recurring or have difficulty remembering it (Madakasira and O’Brien 1987, Cardena and Spiegel 1993, Christianson and Loftus 1987). Thus, physical trauma seems to elicit dissociative responses, which, in turn, predispose to the development of later PTSD, perhaps by reducing the likelihood of working through the traumatic experiences afterward.

**Acute Stress Disorder**

As a result of the line of research just reviewed, a new diagnostic category, acute stress disorder, was included in DSM-IV-TR (American Psychiatric Association 2000). There was an acute stress reaction category in the Diagnostic and Statistical Manual of Mental Disorders, Second Edition (DSM-II), and the International Classification of Diseases, Ninth Revision (ICD-9) has a similar category. It was thought that the inclusion of this diagnosis would facilitate early detection and intervention and would also remedy a hole in the nosology: how to diagnose a substantial minority of victims of acute trauma who are quite symptomatic within the first month after the occurrence of the traumatic stressor.

Although acute stress disorder is classified among the anxiety disorders in DSM-IV-TR (American Psychiatric Association 2000), mention is made of it in this chapter because half of the symptoms of this disorder are dissociative in nature.

This diagnostic criteria would designate approximately a third of individuals exposed to serious trauma as symptomatic. Dissociative symptoms occurring at the time of the trauma are strongly predictive of later development of PTSD (Koopman et al. 1994, Marmar et al. 1994, Classen et al. 1993, Freud 1995) and are associated with higher cortisol levels during exposure to uncontrollable stress (Freud 1958a). Similarly, the occurrence of later PTSD is predicted by the occurrence of symptoms of intrusion, avoidance, and hyperarousal in the immediate aftermath of

---

**DSM-IV-TR Criteria 308.3**

**Acute Stress Disorder**

A. The person has been exposed to a traumatic event in which both of the following have been present:

1. The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
2. The person’s response involved intense fear, helplessness, or horror

B. Either while experiencing or after experiencing the distressing event, the individual has three (or more) of the following dissociative symptoms:

1. A subjective sense of numbing, detachment, or absence of emotional responsiveness
2. Reduction in awareness of his or her surroundings (e.g., “being in a daze”)
3. Derealization
4. Depersonalization
5. Dissociative amnesia (i.e., inability to recall an important aspect of the trauma)

C. The traumatic event is persistently reexperienced in at least one of the following ways: recurrent images, thoughts, dreams, illusions, flashback episodes, or a sense of reliving the experience; or distress on exposure to reminders of the traumatic event.

D. Marked avoidance of stimuli that arouse recollections of the trauma (e.g., thoughts, feelings, conversations, activities, places, people).

E. Marked symptoms of anxiety or increased arousal (e.g., difficulty sleeping, irritability, poor concentration, hypervigilance, exaggerated startle response, motor restlessness).

F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or impairs the individual’s ability to pursue some necessary task, such as obtaining necessary assistance or mobilizing personal resources by telling family members about the traumatic experience.

G. The disturbance lasts for a minimum of 2 days and a maximum of 4 weeks and occurs within 4 weeks of the traumatic event.

H. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition, is not better accounted for by brief psychotic disorder, and is not merely an exacerbation of a preexisting Axis I or Axis II disorder.

Dissociation and Biological Processes

A number of studies have found biological correlates to dissociative disorders. Yet, to date, it is difficult to determine whether these biological changes are the product of dissociative processes or what causes dissociative symptoms.

For example, Simeon et al. (2007) found that compared to normal controls, patients suffering from dissociative disorders exhibited significantly greater resistance to, and faster escape from, dexamethasone suppression. Similarly, the dissociative disorder (DD) group demonstrated a significant inverse correlation between dissociation severity and cortisol reactivity. This study demonstrated a distinct pattern of HPA-axis dysregulation in dissociative disorder (DD) and emphasized the importance of further study of stress-response systems in dissociative psychopathology.

Elzinga et al. (2007) used functional magnetic resonance imaging (fMRI) to assess the working memory in dissociative disorder (DDs) patients during performance of a parametric, verbal working-memory task and compared them to healthy control (HCs) subjects. Imaging data (fMRI) showed that both groups activated brain regions typically involved in working memory (i.e., anterior, dorsolateral and ventrolateral prefrontal cortex (PFC), and parietal cortex) but DDs showed more activation in these areas, particularly in the left anterior PFC, dorsolateral PFC and parietal cortex. As expected, given these findings, DDs also made fewer errors with increasing task load compared to HCs. This study replicated findings of previous studies in nonpathological high dissociative individuals; thus, suggesting that trait dissociation is associated with enhanced working-memory capacities. Similarly, this difference in working memory may help distinguish DDs from patients with PTSD who are generally characterized by impaired working memory.

Dissociation and Memory Systems

There are two broad categories of memory known as explicit and implicit (Schacter 1992), declarative and procedural (Squire 1987), or episodic and semantic (Tulving 1983). These two basic memory systems serve different functions. Explicit or episodic memory involves recall of personal experience identified with the self, for example, “I went dancing last night.” The second type is known as implicit or...
procedural memory. This involves the execution of routine operations, such as driving a car, or typing on a keyboard. Most of these rather automatic operations could be carried out with little conscious awareness, but yet with a high degree of proficiency. These two types of memory seem to reside in different cerebral anatomical localizations. Episodic memory seems to be primarily associated with limbic system function, primarily involving the hippocampal formation and mamillary bodies. On the other hand, procedural memory appears to be a function of basal ganglia and cortical functioning (Kosslyn and Koenig 1992).

The fact that there are separate memory systems may account for certain types of dissociative phenomena (Spiegel et al. 1993). For example, the automaticity observed in certain types of dissociative disorders reflect the separation of self-identification associated with explicit memory from routine activity in implicit or procedural memory. It is thus not at all foreign to our mental processing to act in an automatic way devoid of explicit self-identification. Future research on the neurobiology of memory may well provide insights into the functional disintegration of memory, perception, identity, and consciousness seen in dissociative disorders (Zola-Morgan et al. 1982, Zola-Morgan and Squire 1985).

Comparison of DSM-IV/ICD-10 Diagnostic Criteria
The ICD-10 Diagnostic Criteria for Research for dissociative amnesia specify that there be a “convincing association in time between the onset of symptoms of the disorder and stressful events, problems, or needs.” In DSM-IV-TR, the criteria set notes that the forgotten information is usually of a stressful or traumatic nature.

For dissociative fugue, in contrast to DSM-IV-TR, the ICD-10 Diagnostic Criteria for Research specify “amnesia for the journey.” Furthermore, in contrast to DSM-IV-TR, the ICD-10 Diagnostic Criteria for Research do not indicate that there is an inability to recall one’s past during the fugue or that there be confusion about personal identity.

DID is included in ICD-10 as an example of an “other dissociative (conversion) disorder” under the rubric “multiple personality disorder.” The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical.

Finally, ICD-10 has a single category “depersonalization-derealization syndrome” for presentations characterized by either depersonalization or derealization. In contrast, the DSM-IV-TR category includes only depersonalization and mentions derealization as an associated feature. Furthermore, unlike DSM-IV-TR that includes this category in the dissociative disorders section, ICD-10 includes the category within the “other neurotic disorders” grouping.

Conclusion
The dissociative disorders constitute a challenging and fascinating spectrum of psychiatric illnesses. The failure of integration of memory, identity, perception, and consciousness seen in these disorders results in symptoms that illustrate fundamental problems in the organization of mental processes. Dissociative phenomena often occur during and after physical trauma but may also represent transient or chronic defensive patterns. Dissociative disorders are generally treatable and are a domain in which psychotherapy is a primary modality, although pharmacological treatment of comorbid conditions such as depression can be quite helpful. The dissociative disorders are ubiquitous around the world, although they take a variety of forms. They represent a fascinating diagnostic, therapeutic, and investigative challenge.

References

Preface
To escape from the clinical significance of sexual matters, mental health professionals have to blind and deafen themselves to the importance of these topics:

- Teenage pregnancy, sexual abuse of children and minors, stranger and date rape, HIV infections and other sexually transmitted diseases.
- Abortion, extramarital affairs, commercial sex, sex between physicians and their patients.
- The appeal of Internet pornography and its impact on partner sexual behaviors.
- The consequences of substance abuse, medical illnesses, and psychiatric disorders on the ability to have sex.
- Minor status and unique developmental struggles of gay males, lesbian women, bisexual persons, and the transgendered.
- The sexual side effects of psychotropic medications.
- The role of masturbation in the life cycle.

- The search for an aphrodisiac.
- The regulation of sexual behaviors by religions and governments.

American mental health professionals have been educated within a conservative contradictory sexuality environment. Our personal sexual lives remain guarded even as we are immersed in sexual imagery of youth by various media. This public saturation is not particularly educational; personal sexual concerns remain ubiquitous. When patients look to clinicians for assistance with their sexual worries, they assume that we have a confident knowledgeable comfort with the subject. They are often wrong. For our professional learning to begin, we must allow ourselves to carefully listen to the patient and ask questions, which become more obvious with accumulating clinical experience. Eventually, we discover that some sexual issue lurks behind many psychiatric decompensations. (Figure 77–1)

It is remarkable how silent psychiatric training has been about sexual life since the early 1980s, a span of time during
which the culture learned that sexuality has the potential to generate concerns from childhood to old age. Clinical sexuality thrives best on multiple perspectives. Its scope is too broad for any one scientific profession to master, for any branch of the humanities to have the last word, for any one government’s policy to prevail, or for one religion’s pronouncements to settle a contention.

Humans are not sexually static reproductively-driven mammals. All sexual behavior, solitary and partnered, normal and abnormal, is simultaneously influenced by biological, personal, interpersonal, and cultural forces. Sexual behavior is richly multidetermined. Every person’s sexuality slowly evolves over decades and more rapidly oscillates during short periods of time. Biological maturation and psychological maturation inexorably create different sexual challenges at each life era. You new couples, for instance, typically struggle to orchestrate mutually satisfying intercourse. Ten years later, many are struggling to find time for sex and arguing over its infrequency. Short-term fluctuations are brought about by the inevitable changeability of our biological, psychological, and interpersonal states. Each of us has a dynamic potential to change—from normal to dysfunctional, from dysfunctional to normal, and from ordinary to remarkable.

Despite aspirations to the contrary, medical treatments rest on biases. Urologists emphasize that erectile dysfunction is due to vascular disease. Gynecologists prefer to search for hormone deficiencies for women’s complaints. Psychoanalysts find that early developmental conflicts are limiting adult sexual and love lives. Biological psychiatrists consider excursions of libido to be due to depression or hypomania. Addiction specialists invoke problematic sexual excesses as another symptom requiring a 12-step program. Systems theorists find interpersonal dynamics to be the usual cause of diverse sexual dysfunction. Social psychologists find multigenerational religious guilt a favorite culprit. There is little need for acrimonious debate about etiology of sexual disorders since biological, psychological, interpersonal, and cultural factors are operative in all individuals all the time.

Clinical sexuality has one major recent scientific breakthrough to claim: the new class of drugs for erectile dysfunction known as the PDE-5 inhibitors (Lue 2000). Generally, knowledge of the treatment of sexual disorders is more anecdotal than rigorously evidence based (Heiman 2002). Nonetheless, we seem to be able to provide helpful care for many patients. To be able to be helpful, the psychiatrist needs to be diagnostically competent and skillful with medications—which most are—and interested and willing to talk at length with their patients—which is often not the case.

The Components of Sexuality

An adult’s sexuality has seven components: gender identity, orientation, intention (what one wants to do with a partner’s body and have done with one’s body during sexual behavior), desire, arousal, orgasm, and emotional satisfaction (Levine 1998). The first three components constitute our sexual identity. The second three comprise our sexual function. The seventh, emotional satisfaction, is based on our personal reflections on the first six (Table 77–1: Section I). The DSM-IV-TR designates impairments of five of these components as pathologies. Concerns about orientation and the failure to find sexual behaviors emotionally satisfying
Mechanisms of Sexual Equilibrium

Significance of Sexual Dysfunction

Sexual development through the life cycle

Sexual development through the life cycle

While the psychological foundations for a healthy sexual life are laid down during childhood through parent–child relationships, each subsequent phase of life—adolescence, young adulthood, middle life, and older age—has inherent developmental challenges and potentials (Erikson 1963). The normal tasks of sexual development at each phase provide the clinician with an understanding of age-related etiologies of sexual disorders (Levine 1992). Adolescent sexual troubles often reflect difficulties consolidating a personally acceptable sexual identity (Savin-Williams and Cohen 2004). Young adult dysfunctions often indicate the presence of psychological obstacles to growing comfortable as a sexual pleasure-seeking, pleasure-giving person while integrating sex into the larger context of human attachment. Middle-life disorders often represent failures to maintain psychological intimacy and to diplomatically negotiate tensions within an increasingly complex interpersonal relationship. The dysfunctions of older persons often represent failures to preserve sexual function in the face of biological assaults of menopause, aging, illness, medications, radiation, and surgery. Most etiologic factors can operate in another epoch as well. For instance, a young person’s new indifference to sexual behavior may be due to an SSRI or an older person’s new marriage may expose previously avoided personal discomfort with receiving and giving sexual pleasure.

The Sexual Dysfunctions

Significance of Sexual Dysfunction

Sex is recreation but it is also an important means of establishing and reaffirming emotional attachments. Sexual competence—the ability to desire a partner, become aroused, and attain orgasm in a cooperative manner when together—enables a person to experience the physical pleasures and emotional complexities of love. Sexual behaviors occur more frequently among couples with mutually pleasurable sex than those with unilaterally satisfying behavior. Mutually pleasurable sexual behavior allows both partners to be comforted and stabilized by loving and feeling loved. However they are brought about, sexual dysfunctions limit the sense of competence, participation in one of life’s heralded pleasures, and the sense of feeling stable in relationship to another.

DSM-IV-TR diagnoses

DSM-IV-TR specifies three criteria for each sexual dysfunction. The first criterion describes the psychophysiologic impairment; for example, absence of sexual desire, arousal, or orgasm. The second requires that the patient have marked distress or interpersonal difficulty as a result, while the third asks the clinician to ascertain that some other Axis I diagnosis, medical illness, medication, or substances of abuse does not best explain the problem. Table 77–2 lists the first criterion of each of the 12 sexual dysfunction diagnoses. DSM-IV-TR gives the clinician additional latitude for deciding when a person who meets the first criterion qualifies for a disorder. The doctor is asked to consider the effects of the individual’s age, experience, ethnicity and cultural background, the degree of subjective distress, adequacy of sexual stimulation, and symptom frequency. No data exist to tell us how to exercise this judgment.

Epidemiology

Numerous attempts to describe the prevalence of sexual dysfunction have been made in the previous 25 years. These range from attempts to define the frequency of a particular dysfunction, for instance, male erectile disorder, to attempts to estimate the prevalence of a series of separate dysfunctions; for example, desire, arousal, and orgasmic disorders of women. All such efforts quickly confront methodological influences of sampling, means of obtaining the information, definition of each dysfunction, purpose of the study, and perspective of its authors (Laumann and Michael 2001). These data not surprisingly, therefore, demonstrate a range of prevalence depending on theproblem studied. Gender identity disorders are relatively rare (< 1–2%). Lifelong sexual desire disorders among women may involve up to 15%, but among young men involve up to 5%. Acquired desire disorders among older individuals are probably three times as common as lifelong ones. More than half of women at age 55 years have recognized a decline in their sexual function. Perhaps 25% of women in their 20s have difficulty having orgasm and approximately 33% of men less than age 40 claim to ejaculate too rapidly. The majority of men by age 70 years are likely to be having erection problems. The recent careful epidemiologic study, designed by sociologists, successfully assessed a representative sample of the US (Laumann et al. 1994). They interviewed men and women between age 18 and 59 years and found that sexual function is impaired in 35% of the population, particularly among young women and older men. This is noteworthy for psychiatrists because our studies of sexual dysfunction attributed to medications or new psychiatric disorders tend to assume that patients are generally functionally intact prior to becoming ill or taking medications. This assumption is not tenable. There is a vital distinction to be made, however,
between current prevalence estimates for any dysfunction based on the presence or absence of a particular problem. DSM-IV-TR asks that the diagnosis be based on the presence of distress or impairment and that the problem cannot be attributed to another disorder. Epidemiological data often ignore these criteria. For example, a study may show that 70% of 60-year-old women have diminished sexual desire but only 20% are currently distressed about it. In addition, there is considerable uncertainty whether erectile dysfunction can be entirely explained by depression or social anxiety disorder.

**Sexual Equilibrium**

Etiologic ideas about one individual’s sexual dysfunction are usually less complex than for couples because sexual dysfunction within a stable sexual partnership involves two individual psychologies and biologicals, their interpersonal impact on one another, and their cultures. The clinician must be wary when one coupled person is presented as having a sexual dysfunction and the partner is presented as “normal.” Sexual dysfunction in a couple is a two-person problem in terms of immediate effects and often in terms of cause as well (Table 77–1: Section II). If a partner regards the sexual characteristics of the other is a subtle ingredient of sexual comfort, competence, and dysfunction. For instance, a young woman’s new inability to attain orgasm with her husband may be traced to her embarrassment at sharing her excitation with him because she perceives him to be generally critical of her. Similarly, the origin of a husband’s erectile dysfunction may be traced to the emergence of his wife’s negative regard for him, which stemmed from something other than his sexual behavior. This ordinary connectivity of a couple’s sexual function is referred to as the couple’s sexual equilibrium (Levine 1998). The sexual equilibrium explains five observations:

1. Improvement and deterioration of sexual function can rapidly occur.
2. When a couple’s nonsexual relationship is good, their sexual life may not be.
3. Individual psychotherapy is often insufficient to help coupled patients improve their sexual life.
4. A negative attitude from the partner can block improvement in a couple’s sexual life regardless of the therapy format and therapist skill.
5. A conversation with a therapist who is attuned to the emotional meanings of a couple’s interaction can shift a dysfunctional equilibrium back to mutually satisfying sexual behavior.

**The Nature of Sexual Desire**

We summarize many things under the rubric of sexual desire: erotic fantasies, sexual dreams, initiation of sexual behavior, receptivity to partner-initiated sexual behavior, masturbation, genital sensations, heightened responsivity to erotic environmental cues, and sincere statements about wanting to behave sexually. These are often referred to as manifestations of libido, but this historic term has created the illusion that libido was a homogeneous force. The diverse and changeable desire manifestations are produced by the intersection of three mental forces: drive (biology), motive (psychology), and values (culture) (Levine 2003).
Drive. By only partially understood psychoneuroendocrine mechanisms, the preoptic area of the anterior-medial hypothalamus and the limbic system periodically produce sexual drive in both sexes (Federman 2006). Drive is recognized by genital tingling, heightened responsiveness to erotic environmental cues, plans for self or partner sexual behavior, nocturnal orgasm, and increased erotic preoccupations. These are spontaneous particularly among adolescents and young adults. Although people can become aroused and attain orgasm without evident drive, drive propels the sexual physiological process. Without drive, the sexual response system is less efficient. While men as a group seem to have significant more drive than women as a group, in both sexes, drive requires at least the presence of a modest amount of testosterone. Drive is frequently dampened by medications that act within the central nervous system, substances of abuse, psychiatric illness, systemic physical illness, despair, and aging. It is heightened by low doses of a few often-abused substances such as alcohol or amphetamine, manic mechanisms, falling in love, joy, and some drugs for Parkinson’s disease.

Motive. The psychological aspect of desire is referred to as motive and is recognized by willingness to bring one’s body to the partner for sexual behavior either through initiation or receptivity. Motive often directly stems from the person’s perception of the context of the nonsexual and sexual relationship. Sexual desire diagnoses are made in persons who have adequate drive manifestations and those who apparently have none. Most sexual desire problems in physically healthy adults are generated by one partner’s unwillingness to engage in sexual behavior. This is often kept secret, however, from the partner because the reason for the unwillingness would have to be explained; something that the patient may not be ready to do.

Values. Sexual motives are originally programmed by social and cultural experiences. Children and adolescents acquire values—beliefs, expectations, and rules—for sexual expression. Young people have to negotiate their way through the fact that their early motives to behave sexually frequently coexist with their motives not to engage in sexual behavior. Conflicted motives often persist throughout life but the reasons for the conflict evolve. A teenager possessed of considerable drive and motive to make love may inhibit all sexual activities because of religiously acquired moral considerations or the sense that he or she is just not ready yet.

Two practical dimensions of the values’ contribution to sexual desire are embodied in the answers to two questions most people consider when sex is in the offering: “Is this behavior normal?” and “Is this behavior normal?”

For a young teenager, “Is the behavior normal?” often refers to masturbation and the person may not be certain that it is normal. In a few years, however, he or she may learn that it is normal and then masturbation will commence without worry. An older person may state that he has no desire for extramarital sex when in fact he is solely tempted and recurrently excited by a particular person. His statement reflects his sense that he does not wish to succumb to an act that he considers to be immoral.

The appearance and disappearance of sexual desire is often enigmatic to a patient, but its ebb and flow result from the ever-changing intensities of its components, biological drive, psychological motive, and socially acquired values (Table 77–3) (Levine 2003). In young and middle-aged men drive manifestations tend to lead to behaviors that cause arousal. In comparably aged partnered women, it is often the partners’ initiations that occur first and then induce arousal, which leads to women’s motives to behave sexually (Basson 2000).

**Clinical Vignette**

A 51-year-old secretary explained that she had had a wonderful sexual life with her husband until she humorously asked whether he had ever had an affair during their 20-year marriage. He shocked her by confessing a past “insignificant” one. As she thought about this over a week, she became increasingly enraged and asked him to leave the home. Several weeks later, he came back after constant phone contact and in response to her coming down with a flu-like illness. When their sexual behavior resumed 2 months later, she became the “ice queen”—unable to stand his touches. Her aversion lasted 6 months. Four years later when she discovered that he was having an affair, she redeveloped her aversion, adding that she felt that he was raping her when he touched her and that she could not...
Sexual Desire Diagnoses

Two official diagnoses are given to men and women whose desires for partner sexual behavior are deficient: hypoactive sexual desire disorder (HSDD) and sexual aversion disorder (SAD). The differences between the two revolve around the emotional intensity with which the patient avoids sexual behavior. When visceral anxiety, fear, or disgust is routinely felt as sexual behavior becomes a possibility, sexual aversion is diagnosed. HSDD is far more frequently encountered. It is present in at least twice as many women than men; female-to-male ratio for aversion is far higher. Like all sexual dysfunctions, the desire diagnoses may be lifelong or may have been acquired after a period of ordinary fluctuations of sexual desire. Acquired disorders may be partner specific (“situational”) or may occur with all subsequent partners (“generalized”).

Hypoactive Sexual Desire Disorder

A. Persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. The judgment of deficiency or absence is made by the clinician, taking into account factors that affect sexual functioning, such as age and the context of the person’s life.

B. The disturbance causes marked distress or interpersonal difficulty.

C. The sexual dysfunction is not better accounted for by another Axis I disorder (except another sexual dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Due to psychological factors
Due to combined factors

When the psychiatrist concludes that the patient’s acquired generalized HSDD is either due to a medical condition, a medication, or a substance of abuse, the diagnosis is further elaborated to sexual dysfunction due to general medical condition or substance-induced sexual dysfunction (e.g., HSDD due to multiple sclerosis). The frequency of the specific etiologies is heavily dependent on the clinical setting. In oncology settings, medical causes occur in high frequency; in drug rehabilitation programs, methadone maintenance will be a common cause. In marital therapy clinics, anger and loss of respect for the partner, hidden incompatibility of sexual identity between the self and the partner because of covert homosexuality or paraphilia, an affair, or childhood sexual abuse will commonly be the basis. In general psychiatry settings, medication side effects will often be the top layer of several causes. When a major depressive disorder is diagnosed, for instance, the desire disorder is often assumed to be a symptom of the depression. This usually is incorrect. The desire disorder often precedes the decompensation into depression.

From a Desire Diagnosis to Dynamics

Those with lifelong deficiencies of sexual desire are often perceived to be struggling with either: (1) sexual identity issues involving gender identity, orientation, or a paraphilia; (2) having failed to grow comfortable as a sexual person due to extremely conservative cultural backgrounds, developmental misfortunes, or abuses. Occasionally, the etiology is enigmatic, raising the important question whether it is possible to never have any sexual drive manifestations on a biological basis. (Theoretically, the answer is yes.) Both acquired and lifelong desire disorders are often associated
with past or chronic mood disorders. Disorders of desire are often listed as “of unknown etiology” (Rosen and Leiblum 1995), but clinicians should be skeptical of this idea because

1. the patient may not tell the doctor the truth early in the doctor–patient relationship;
2. the patient may have strong defenses such as repression against knowing the truth;
3. the patient may not be able to speak freely in front of the partner;
4. the patient may be influenced by the unappreciated stresses in the partner;
5. the doctor may not realize the usual causes of the problem;
6. the doctor may not believe in developmental influences on the organization of adult sexual function.

A patient presenting with SAD should strongly suggest four possibilities to the clinician:

1. that a remote traumatic experience is being relived because of the partner’s expression of interest in sexual behavior;
2. that without the symptom the patient feels powerless to say “no” to sexual advances;
3. the patient is angry at the partner but is too afraid to state why;
4. the patient feels guilty about his or her own sexual behavior with another person.

The doctor’s attention should focus on the patient’s sexual development as a child, adolescent, and young adult when the aversion is lifelong, whereas when it is acquired, the focus of the history should be on the period immediately prior to the onset of the symptom.

Desire disorders require the clinician to think both in terms of development and personal meanings of sex to their individual patients (Table 77–4). Because all explanations are speculative, they should at least make compelling sense of the patients’ life experiences. Some explanations

are based on the influence of remote developmental processes. The term "Madonna-whore complex" misleads us into thinking that this is only a male pattern. The syndrome is manifested by normal sexual capacity with anyone but the fiancé or spouse. Freud interpreted this as a sign of incomplete resolution of the oedipal complex (Freud 1912). The man was thought to be unable to sexually desire his beloved because he had unconsciously equated her with his mother. He withdrew his sexual interest from her to protect himself from symbolic incest. Some women are comparably unable to sexually enjoy their partners because they unconsciously confuse their beloved with their father. Another form can be seen among patients whose parents were grossly inadequate caregivers. When these men and women find a reliable, kind, supportive person to marry, they quickly discover a strong motive to avoid sexual behavior with their fiancé. The patient makes the partner into a good-enough parent, experiences anxiety as an unconscious threat of incest associated with the possibility of sex, and becomes skillful at avoiding sexual opportunities.

Most sexual desire disorders are difficult to quickly overcome in brief treatments. Serious individual or couple issues frequently underlie these diagnoses. They have to be afforded time to emerge and to be worked through. However, clinicians need not be pessimistic (Hall 2005). For example, helping a couple resolve a marital dispute may return them to their usual normal sexual desire manifestations. For many individuals and couples, therapy assists the couple to more calmly accept the profound implications of continuing marital discord, infidelity, homosexuality, or other contributing factors. Some treatment failures lead to divorce and the creation of a relationship with a new partner. There is then no further sign of the desire problem. Problems rooted in early developmental experiences are particularly difficult to overcome. While DSM-IV-TR asks the clinician to make many distinctions among the desire disorders, no follow-up study has been published in which either the subtypes (life-long, acquired, situational, generalized) or etiologic organizers (relationship deterioration with and without extra-marital affairs, sexual identity incompatibilities, parental, and medical) are separated into good and poor prognosis categories.

Developmental and identity matters are typically approached in long-term individual psychotherapy. In these sessions, women often discuss the development of their femininity from adolescence to young womanhood, focusing on issues of body image, beauty, social worth to others, moral sensibilities, social awkwardness, and whether they consider themselves deserving of personal physical pleasure. Men often discuss similar issues in terms of masculinity.

Anger, loss of respect, marital discord, and extramarital affairs may be approached in either individual or conjoint formats. In either setting, patients often formulate

---

**DSM-IV-TR Criteria**

**Substance-Induced Sexual Dysfunction**

A. Clinically significant sexual dysfunction that results in marked distress or interpersonal difficulty predominates in the clinical picture.

B. There is evidence from the history, physical examination, or laboratory findings that the sexual dysfunction is fully explained by substance use as manifested by either (1) or (2):

1. the symptoms in criterion A developed during, or within a month of, substance intoxication
2. medication use is etiologically related to the disturbance

C. The disturbance is not better accounted for by a sexual dysfunction that is not substance induced. Evidence that the symptoms are better accounted for by a sexual dysfunction that is not substance induced might include the following: the symptoms precede the onset of the substance use or dependence (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of intoxication, or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence that suggests the existence of an independent non-

---

substance-induced sexual dysfunction (e.g., a history of recurrent non-substance-related episodes).

Note: This diagnosis should be made instead of a diagnosis of substance intoxication only when the sexual dysfunction is in excess of that usually associated with the intoxication syndrome and when the dysfunction is sufficiently severe to warrant independent clinical attention.

**Code** [specific substance]-induced sexual dysfunction:

(291.8 Alcohol; 292.89 Amphetamine [or Amphetamine-like Substance]; 292.89 Cocaine; 292.89 Opioid; 292.89 Sedative, Hypnotic, or Anxiolytic; 292.89 Other [or Unknown] Substance)

**Specify if:**

- With impaired desire
- With impaired arousal
- With impaired orgasm
- With sexual pain

**Specify if:**

With onset during intoxication: if the criteria are met for intoxication with the substance and the symptoms develop during the intoxication syndrome.
The Problems of Sexual Arousal

The emotion interchangeably referred to as sexual arousal or sexual excitement generates changes in respiration, pulse, and muscular tension as well as an increased blood flow to the genitals. Genital vasodilatation creates vaginal lubrication, clitoral tumescence, labial color changes, penile erection, testicular elevation, and penile color changes (Masters and Johnson 1966). How arousal is centrally coordinated in either sex remains mysterious. During lovemaking, men and women do not necessarily maintain or progressively increase their arousal; rather often there is a fluctuating intensity of arousal, which is reflected in variations in vaginal wetness and penile turgidity and non-genital signs of arousal.

Female Sexual Arousal Disorder (FSAD)

The specificity and validity of this disorder is unclear. In women, it is far more difficult to separate arousal and desire problems than in young men. New desire/arousal problems arise typically in the middle-to-late 40s in up to 50% of women as perimenopausal vaginal lubrication diminishes (Grady 2006). It is assumed to be endocrine in origin even though estrogen treatment only reliably improves the symptoms relating to vaginal moisture deficiency. The disorder is also seen among regularly menstruating women, who claim that they desire sex but simply do not become aroused with the same efficiency and intensity. Making the diagnosis of FSAD implies that drive and motivation are relatively intact. The disorder is typically an acquired one. The women focus on the lack of moisture in the vagina or their failure to be excited by the behaviors that previously reliably brought pleasure. Assuming that some mental factor distracts them from excitement during lovemaking, therapy focuses on identifying what this might be (Basson 2003).

In menopausal women, FSAD is more often focused on the body as a whole rather than just genital moisture deficiencies. Skin insensitivity, often a euphemism for decreased pleasure in response to oral and manual nipple, breast, and vulvar stimulation, is often initially treated as a symptom of “estrogen” deficiency. Early in the menopause, a small minority of women have an increase in drive due to changing testosterone–estrogen ratios. Yet, they may still subjectively experience arousal as subjectively different. Therapy often focuses on the women’s concerns about estrogen replacement and the consequences of menopause in terms of body image, attractiveness, fear of partner infidelity, loss of health and vigor, and aging.

Aging of the female arousal mechanisms, whether simply due to shifts in ovarian steroid production or systemic aging mechanisms, occurs earlier than deterioration of orgasmic physiology. Women with decreasing arousal are often, therefore, still reliably orgasmic with the use of vaginal lubricants (Basson 2006). Women who have been treated with chemotherapy for various cancers are a particularly problematic group to offer assistance to for their new arousal problems. Fear of stimulating estrogen sensitive breast cancer cells, increasing the risk of thromboembolic phenomena, stroke, and myocardial infarction has dramatically limited the use of estrogen/progesterone replacement (WHI Writing Group 2002).

The use of PDE-5i drugs for erectile dysfunction stimulated an ongoing search for medications for HSSD and FSAD. Thus far, no single compound, including sildenafil, has been able to demonstrate effectiveness in placebo-controlled studies (Basson et al. 2002).

Here is a relatively simple case of an acquired arousal disorder that was most likely a combination of perimenopausal biological changes and more important psychological ones.

A regularly menstruating 50-year-old widow complained of difficulty with arousal with her new “good-enough” lover. She was motivated to behave sexually with him but something seemed to have happened to her since her husband developed a brain tumor and died and she spent 2 years without dating. Her body, which used to work well sexually, had ceased to be reliably sexually functional. She was intermittently vaginally dry despite using a lubricant, she had trouble sustaining excitement, and orgasm only occasionally occurred with great effort. She could masturbate efficiently when alone, but was not motivated to do it—“What good is it?” Not depressed clinically, she was baffled by her failure to adapt to her new situation. Her conversation with the therapist wove together
two themes: the unusually happy life she had with her husband who tragically died so young leaving her to grieve forever and her musings about the meaning of her new lover’s wife’s suicide. “Let’s face it, as nice as he is, he is no George.”

Male Erectile Disorder (ED)
The mechanisms of sequestering and maintaining arterial blood within the corpora cavernosa involve both cAMP and cGMP biochemistry. The advent of the PDE-5i’s has diminished the emphasis on psychogenic versus organic ED and the urological/psychological turf wars of the past. While it is widely recognized that young men more commonly have pure psychogenic ED and men over 50 often have significant organic contributants, some younger men have organic factors and some older men have significant psychological and interpersonal reasons for their inability to sustain potency. It is important for mental health professionals to realize that the PDE-5i class of medications, while capable of curing the problem in many individuals, often only slightly helps. Psychiatric attention is often still required because the sexual context can become in some subtle ways too dangerous, frightening, or otherwise unwanted for men to be potent with a particular partner.

The prevalence of ED rises dramatically in the sixth decade of life from less than 10 to 30%; it increases further during the seventh decade (Feldman et al. 1994). Aging, medical conditions such as diabetes, prostate cancer, hypertension, and cardiovascular risk factors predict the most common pattern of ED due to a medical condition in this age group. While medication-induced, neurological, endocrine, metabolic, radiation, and surgical causes of erectile dysfunction also exist, in population studies diabetes, hypertension, smoking, lipid abnormalities, obesity, and lack of exercise are correlated with the progressive deterioration of erectile functioning in the sixth and seventh decades. These factors are thought to create a relative penile anoxemia, which stimulates the conversion of corporal smooth muscle cells into fibrocytes. The gradual loss of elasticity of the corpora interferes with filling and sequestering of arterial blood (Carrier et al. 1993). Erections at first become unreliable and finally impossible to obtain or sustain.

At every age, selectivity of erectile failure is the single most important diagnostic feature of psychogenic erectile dysfunction. Clinicians should inquire about the relative firmness and duration of erections under each of these circumstances: masturbation, sex other than intercourse, sex with other female or male partners, upon stimulation with explicit media materials, in the middle of the night, and upon awakening. If under some circumstances the erection is firm and lasting, the clinician can usually assume that the man’s neural, endocrine, and vascular physiology is sufficiently normal and that the problem is psychogenic in origin. This is true even for men in their 50s and older (Levine 2004). Clinicians often feel more certain about this diagnosis when no diseases thought to lead to erectile dysfunction are present.

Clinical Vignette 2

A 35-year-old man who is potent reliably with his wife becomes sexually anxious when he attempts to have intercourse with a new partner. During foreplay with her, he has been lastingly erect. But when he attempts to penetrate she does so with a softening erection and it becomes a race between rapid ejaculation and loss of erection.

Patient: “What is going on here doctor?”
Doctor: “What is going on here?”
Patient: “I know there is nothing wrong with me physically.”
Doctor: “Me, too. So why did you spend so much time with the urologist?”
Patient: “I guess I did not want to face what I am doing about my wife and children and my resentment of being confined by marriage.”

Lifelong male ED typically is psychogenic and involves either a sexual identity dilemma—such as, gender identity disorder, a hidden-from-wife homoerotic orientation, a paraphilia, or another diagnosis associated with the man’s fear of being sexually close to a partner such as some instances of obsessive–compulsive disorder, schizoid personality, a psychotic disorder, or borderline personality disorder. Sexual identity problems are often initially denied unless the clinician is nonjudgmental and thorough during the inquiry. Occasionally, a reasonably normal young man with an unusually persistent fear of sexual intercourse seeks attention.
In dramatic contrast, men with long-established good potency who have recently lost their erectile capacities with their partner—acquired psychogenic ED—have a far better prognosis (Table 77–6). They may be treated in individual or couples format, depending on the precipitants of the sexual problem and the status of their relationship with their partner. Many of these therapies become focused on resentments that have not been identified, discussed, and worked through by the couple. Such distressed couples are most efficiently helped in a conjoint format. When extra-marital affairs are part of the relationship deterioration and cannot be discussed, most clinicians simply work with one spouse. Potency is frequently lost following a separation or divorce. Impaired potency after a spouse’s death is usually about unresolved grief, but the clinician should be aware that some of these men had the same problem with their wives. Men also often get worried about their potency when their financial or vocational lives crumble, when they have a serious new physical illness such as a myocardial infarction or stroke, or when their wives become seriously ill. The esthetics of lovemaking requires a context of reasonable physical health; when one spouse becomes chronically ill or disfigured by illness or surgery, either one of the couple may lose their willingness to be sexual. This may be reflected in impaired erections or sexual avoidance.

Regardless of the precipitating factors, men with arousal disorders have performance anxiety. They anticipate erectile failure before sex begins and vigilantly monitor their state of tumescence during sex (Masters and Johnson 1970). Performance anxiety is present in almost all impotent men (and after any dysfunction gets established in men or women). Performance anxiety is efficiently therapeutically addressed by pointing it out to the patient and asking him to make love without trying intercourse on several occasions to demonstrate to himself how different lovemaking can feel for him when he is not risking failure. This enables some men to relax, concentrate on sensation, and return to previous states of sexual abandon during lovemaking. This technique is known as sensate focus.

The psychological treatment of acquired ED is often highly satisfying for the professional because many of the men are anxious for help. Motivation to behave sexually

### Table 77–6

**Apparent Precipitants of Recently Acquired Psychogenic Erectile Dysfunction and Their Associated Private Emotions***

| Deterioration of marital relationship: anger, guilt, disdain, sadness |
| Divorce: abandonment, anger, guilt, sadness, shame |
| Deterioration of personal or spousal health: sadness, anxiety, anger, shame |
| Death of spouse (“widower’s impotence”): sadness, longing, guilt |
| Threat of or actual unemployment: anxiety, worthlessness, guilt, anger, shame |
| Financial reversal: shame, guilt, anxiety |
| Surrogate extramarital affair: guilt |
| Reunited marriage after extramarital affair: shame, anxiety |

*These short lists of emotions are a mere introduction to what transpires within the man’s mind as a result of the meanings that the sexual behavior has for him. Although incomplete and oversimplified, they are listed to remind the psychiatrist that what the man feels about his life competes with sexual arousal during sexual behavior to diminish the secretion of nitric oxide in the cavernosal endothelial cells, which in turn limits the amount of vasodilating cGMP.

---

These good prognosis cases are sometimes informally referred to as anxious beginners (Table 77–5). With that exception, men with lifelong ED, when taken into individual therapy, are usually perceived as having a strong motive to avoid sexual behavior and while dysfunctional with a partner during much of their therapy might also appropriately be diagnosed as having HSDD with normal drive but with a motive to avoid partner sex. The prognosis with older men with lifelong erectile dysfunction is poor even with modern erectile agents. Long-term therapy, even if it does not enable regular intercourse, may enable more emotional and sexual closeness to a partner. Some reasonably masculine appearing men with mild gender identity problems can quickly become potent if they can reveal their need during sexual relationship to cross-dress (use a fetish article of clothing) to a partner who calmly accepts his requirement. Performance anxiety is efficiently therapeutically addressed by pointing it out to the patient and asking him to make love without trying intercourse on several occasions to demonstrate to himself how different lovemaking can feel for him when he is not risking failure. This enables some men to relax, concentrate on sensation, and return to previous states of sexual abandon during lovemaking. This technique is known as sensate focus.

The psychological treatment of acquired ED is often highly satisfying for the professional because many of the men are anxious for help. Motivation to behave sexually

---

*These short lists of emotions are a mere introduction to what transpires within the man’s mind as a result of the meanings that the sexual behavior has for him. Although incomplete and oversimplified, they are listed to remind the psychiatrist that what the man feels about his life competes with sexual arousal during sexual behavior to diminish the secretion of nitric oxide in the cavernosal endothelial cells, which in turn limits the amount of vasodilating cGMP.
is often present, fear can be allayed, and men can learn to appreciate the emotional complexity of their lives. They can be shown how their minds prevented intercourse until they could acknowledge what has been transpiring within and around them. Many recently separated men, for example, are grieving, angry, guilty, uncertain, and worried about their finances. Yet, they may propel themselves into a new relationship. Two characteristics seem to predispose to erectile problems at key life transitions: (1) the pursuit of the masculine standard that men ought to be able to perform intercourse with anyone, anywhere, under any circumstances; (2) the inability to readily grasp the nature and significance of his inner experiences. “Yes, my schizophrenic daughter became homeless in another city, my wife was depressed and began drinking to excess in response, and I had a financially costly affair with my secretary. What do these have to do with my loss of potency?” (Table 77–7.)

The phosphodiesterase type 5 inhibitors, sildenafil, vardenafil, and tadalafil maintain corporal vasodilation by preventing the degradation of cGMP. Sexual arousal is not generated by these medications. Arousal is brought about by fantasy, masturbation, anticipation, or partner interaction, and leads to the corporal secretion of nitric oxide, which is converted by an enzyme into cGMP, which relaxes the smooth muscle of the capillaries and decreases the resistance to blood flow. No PDE-5i should be used when any organic nitrate is being taken because it dangerously potentiates the hypotensive effect of the nitrates risking brain and myocardial infarction (Goldstein et al. 1998). The PDE-5i drugs are underutilized by psychiatrists for three major reasons: psychiatrists often have not been well trained in sexual history taking so they remain uncomfortable talking to their patients about sexual issues in detail, they needlessly fear cardiac side effects from these medications, and drug manufacturers have targeted primary care physicians and urologists with their educational efforts because they are men’s first medical contacts for this symptom.

Three conditions have unique response profiles to PDE-5i’s: after prostatectomy the response rate is approximately 34%, among diabetics it is approximately 43%, and among those with pure psychogenic ED it is approximately 80%. Other interventions are effective in varying degrees for largely organic erectile dysfunction: vacuum pump, the intracavernosal injection of vasodilating substances (cAMP mechanism), intraurethral alprostadil, the surgical implantation of a penile prostheses, and outside the US, sublingual apomorphine. Because the rate of improving erections is significantly higher than the restoration of a mutually satisfactory sexual equilibrium with the PDE-5i class of drugs, mental health professionals still have a role to play (Leiblum 2002, Levine 2006, Pallas et al. 2000)

### Problems with Orgasm

#### Female Orgasmic Disorder

The attainment of reasonably regular orgasms with a partner is a crucial personal developmental step for young women. This task of adult sexual development rests upon a subtle interplay of physiology, individual psychology, and culture. Reliable orgasmic attainment is usually highly valued by the woman and is often reflected in enhanced self-esteem, confidence in her femininity, relationship satisfaction, and the motive to continue to behave sexually.

Orgasm is the reflexive culmination of arousal. It is manifested by rhythmic pelvic floor musculature contractions followed by the release of muscular tension and pelvic vasocongestion, accompanied by varying degrees of pleasurable body sensations. Its accomplishment requires (1) the physiologic apparatus to augment and sustain arousal, (2) the psychological willingness to be swept away by excitement, and (3) tenacious focus on the required physical work of augmenting arousal. The diagnosis of female orgasmic disorder is made when the woman’s psychology persistently interferes with her body’s natural progression through arousal (Meston et al. 2004).

Estimates of prevalence of both lifelong and acquired psychological FOD range from 10 to 30% (Laumann et al. 1999) but the most common estimate is ~25%. Some of this variability is due to the different definitions of anorgasmia. It remains a difficult scientific judgment, however, where to draw the line between dysfunction and normality; for example, is it normal to attain orgasms during one-third of partner sexual experiences? Few women are always orgasmic.

The biologic potential for orgasmic attainment is an inborn endowment of nearly all physically healthy women. The cultural and psychological factors that influence orgasmic attainment are usually fundamental to the etiology of this problem. Centuries-old beliefs that sexual knowledge, behavior, and sexual pleasure were not the prerogative of “good girls” powerfully affect some women’s sexual adjustment. These beliefs cause young women to be uninformed about the location and role of their clitoris and ashamed of their erotic desires and sexual sensations. For women with FOD, modern concepts of equality of sexual expression are insufficient to overcome these traditional beliefs. These emotionally powerful beliefs often lay behind their classic dysfunctional pattern: the women can become aroused to a personal plateau beyond which they cannot progress;

Female Orgasmic Disorder

A. Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. Women exhibit wide variability in the type or intensity of stimulation that triggers orgasm. The diagnosis of female orgasmic disorder should be based on the clinician’s judgment that the woman’s orgasmic capacity is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives.

B. The disturbance causes marked distress or interpersonal difficulty.

C. The orgasmic dysfunction is not better accounted for by another Axis I disorder (except another sexual dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Diagnosis

The doctor should know the answers to the following questions. Does the patient have orgasms under any of the following sexual circumstances: solitary masturbation, partner manual genital stimulation, oral–genital stimulation, vibratory stimulation, any other means? Does she have orgasms with a partner different than her significant other? How are they stimulated? Does a particular fantasy make orgasmic attainment easier or possible? Under what conditions has she ever been orgasmic? Has she had an orgasm during her sleep?

Lifelong Varieties

The lifelong generalized variety of the disorder is recognized when a woman has never been able to attain orgasm alone or with a partner by any means, although she regularly is aroused. When a woman can only readily attain orgasm during masturbation, she is diagnosed as having a lifelong situational type. Women with any form of lifelong FOD more clearly have conflicts about personal sexual expression due to fear, guilt, ignorance, or obedience to tradition than those with the acquired variety. Women who can masturbate to orgasm often feel fear and embarrassment about sharing their private arousal with any other person.

Acquired Varieties

The acquired varieties of this disorder are more common and may present as complete anorgasmia, too-infrequent orgasms, or too-difficult orgasmic attainment. The most common cause of this problem is serotonergic compounds. Prospective studies of various antidepressants have demonstrated up to 70% incidence of this disorder among those treated with serotonergic antidepressants. When medications are not the cause of an acquired FOD, the doctor needs to carefully assess the meaning of the changes in her life prior to the onset of the disorder. Some of these women are in the midst of making a transition to a new partner after many years in another relationship. Some seem to suffer from memories of earlier shame-ridden behaviors such as incest. It is likely that psychotherapy with a number of patients will reveal a range of reasons for their inhibitions.

Treatment

When a doctor applies a label of disorder to a relatively anorgasmic woman, the woman often privately interprets the diagnosis as meaning that she has a serious and difficult problem to overcome. Physicians need to be careful about this because some of these women are relatively easy to help. It must be realized that many women gradually undo the effects of their culture on their own and grow to be increasingly responsive sexually with time and growing trust of their partners. Clinicians can do many women a great service by offering education and reassurance. Giving an inhibited woman new-to-her information in an encouraging manner can subdue her anxiety and foster her optimism. On the other hand, some women with this disorder are profoundly entrenched in not being too excited and consequently treatments fail. The prognosis is better with younger adults than middle-aged women.

Four formats are known to be of help. Individual therapy is the most commonly employed. In lifelong varieties of the disorder, therapy focuses on the cultural sources of sexual inhibition and how and when they impacted upon the patient. In the situational varieties, the therapist focuses on the meaning of the life changes that preceded the onset of the disorder. Group therapy is highly effective in helping women to reliably masturbate to orgasm and moderately effective in overcoming partner inhibition. It is typically done with college and graduate students in campus settings, not older women. Couple therapy may be useful to assist the couple with the subtleties of their sexual equilibrium. The personal and interpersonal dimensions of orgasmic attainment can be stressed. Often other issues then come to the fore that initially seemed to have little to do with orgasmic attainment. The most cost-effective treatment is bibliotherapy. Female orgasmic attainment has been widely written about in the popular press since the early 1970s. It is widely believed that these articles and books, which
strongly encourage knowledge of her genital anatomy, masturbation, and active pursuit of orgasm, have enabled many women to grow more comfortable and competent in sexual expression. Only recently has the science behind orgasmic attainment been placed on firmer footing with PET and fMRI study (Kamisarek et al. 2006). They have discovered that multiple areas in the brain are activated during orgasm.

**Male Orgasmic Disorder**

When a man can readily attain a lasting erection with a partner, yet is consistently unable to attain orgasm in the body of the partner, he is diagnosed with male orgasmic disorder (MOD). The disorder has three levels of severity: (1) the most common form is characterized by the ability to attain orgasm with a partner outside of her or his body, either through oral, manual, or personal masturbation; (2) the more severe form is characterized by the man’s inability to ejaculate in his partner’s presence; and (3) the rarest form is characterized by the inability to ejaculate when awake. All three forms are usually lifelong and not partner specific. These men cannot allow themselves to be swept away in arousal by another person. They are sexually vigilant to not allow themselves to be controlled by the partner’s power to convey them to orgasm. Male orgasm is expected by their female partners. It provides the woman the pleasure and validation of being exciting to the man. While she may have felt that her new partner was a sexual superman during the first several experiences with him, ultimately she is disappointed and loses her sexual motivation to make love to him. Clinicians, therefore, need to remember that the loss of sexual desire may be induced by the presence of a partner’s dysfunction. Both the partners and the therapists of these men tend to describe them as controlling, unemotional, untrusting, hostile, obsessive-compulsive, or paranoid. Some of these men get better with psychotherapy, others improve spontaneously with time, and, for others the dysfunction leads to the cessation of the aspiration for sex with a partner. Medication treatments have shown inconsistently disappointing results.

**Premature Ejaculation**

Premature ejaculation is a high prevalence (25–40%) (Laumann et al. 1999) disorder seen primarily in heterosexuals characterized by an untamely low threshold for the reflex sequence of orgasm. The problem, a physiological efficiency of sperm delivery, causes social and psychological distress. In failing to develop a sense of control over the timing of his orgasm in the vagina, the man fails to meet his standards of being a satisfying sexual partner. However, if his partner does not object, his rapidity is not likely to cause him to seek medical attention. The range of intravaginal containment times among self-diagnosed patients extends from immediately before or upon vaginal entry (rare), to less than a minute (usual), to less than the man and his partner desire within ~5 minutes (not infrequent). Time alone is a misleading indicator, however. The essence alone is a misleading indicator, however. The essence of the self-diagnosis is an emotionally unsatisfying sexual equilibrium apparently due to the man’s inability to temper his arousal and choose when he ejaculates. Most men sometimes ejaculate before they wish to, but not persistently.

---

**DSM-IV-TR Criteria**

**Premature Ejaculation**

A. Persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity.

B. The disturbance causes marked distress or interpersonal difficulty.

C. The premature ejaculation is not due exclusively to the direct effects of a substance (e.g., withdrawal from opioids).

**Clinical Approach**

The history should clarify the answers to the following questions. Why is he seeking therapy now? Is the patient a sexual beginner or a beginner with a particular partner? Does he have inordinately high expectations for intravaginal containment time for a man his age and experience? Is he desperate about losing the partner because of the rapid ejaculation? Is the relationship in jeopardy for another reason? Does his partner have a sexual dysfunction? Does she have orgasms with him other than through intercourse? Is he requesting help to support his wife’s misperception that their sexual problems are his fault when in fact he does not have the problem with his lover? Is his partner now blaming the man’s sexual inadequacy for her infidelity? Is his new symptom a reflection of his fear about having a serious physical problem during sex such as angina, a stroke, or another myocardial infarction? The answers will enable the doctor to classify the rapid ejaculation into an acquired or lifelong and specific or general pattern, to sense the larger context in which his sexual behavior is conducted, and to plan treatment.

Premature ejaculation reflects to the man’s sense that his contribution to the sexual equilibrium is deficient. It implies that he considers that he is far behind most men in his vaginal containment time and that he wants to provide his partner with a better opportunity to be nurtured during lovemaking through prolonged intercourse. Typically, he
aspires to "bring" his partner to orgasm during intercourse. If anxiety lowers the ejaculatory threshold and keeps it from its natural evolution to a higher level over time, then premature ejaculation may last a lifetime even though some men with premature ejaculation have sex with a variety of partners under a variety of circumstances and have no problems with any other phase of sexual physiology (Waldinger 2003).

**Therapy**

There are three efficient approaches to this dysfunction. The first is simply to refuse to confirm the patient's self-diagnosis. Some anxious beginners, men with reasonable intravaginal containment times of 2 or more minutes, and those with exaggerated notions of sexual performance can be calmed down by a few visits. When they no longer think of themselves as dysfunctional their intravaginal containment times improve. The second is the use of serotonergic medications. In a study of 15 carefully selected stable couples, daily administration of clomipramine 25 and 50 mg increased intravaginal containment times on average of 249% and 517% over baseline observations (Althof et al. 1995). Numerous similar reports testify to the fact that various serotonergic reuptake inhibitors can lengthen the duration of intercourse and have led to a search for an ideal SSRI to treat premature ejaculation. Thus far, no compound has been approved by the FDA for this purpose. With this off-label use of serotonergic drugs, clinicians need to determine with each patient whether the medication can be taken within hours or days of anticipated intercourse. Improvement is not sustained after medication is stopped. Serotonergic medications are quickly effective in over 90% of men. The third approach is behaviorally oriented sex therapy that trains the man to focus his attention on his penile sensations during vaginal containment and to signal his partner to cease movement or to apply a firm squeeze of the glans/shaft area to interrupt the escalation of arousal. This requires an increase in communication and full cooperation of the partner, which in themselves can go a long way in improving the couple's sexual equilibrium.

Rapid ejaculation in some men reflects mere inexperience; for others it is stubborn physiological efficiency; for some others it reflects fear of personal harm, which is either related to physical illness or to unresolved fears of closeness to a woman; and yet for others it reflects a partnership with a profoundly inhibited blaming partner. If the psychodynamic question is asked of men with persistent rapid ejaculation "Why does this man want to finish intercourse so quickly?" the answers vary from, "It is not a relevant question!" to "I'm afraid of her!" to "I'm afraid of what will happen to me." For instance, a large percentage of men ejaculate quickly for the first months after a myocardial infarction. The advantages of costlier couple psychotherapy are to allow the man and his partner to understand their lives better, to address both of their sexual anxieties, and to deal with other nonsexual issues in their relationship. Effective psychotherapy allows the man to become positioned to continue the usual biological evolution that occurs during the life cycle from rapid ejaculation, which is true for many young men, to occasional difficulty in ejaculating, which is true for many men in their 60s.

**Sexual Pain Disorders**

Here are some pertinent questions to ask a young woman who reports painful intercourse. Does she have a gynecologic abnormality that is generally associated with pain, such as endometriosis? Does she know herself to have a low pain threshold? Does she have another pain disorder such as fibromyalgia? Did the pain or the aversion to sexual intercourse come first? Is it possible to actually deeply penetrate her vagina with a penis, a finger, a tampon, or a penis-shaped object? Does her partner's sexual style cause her physical or mental discomfort; for example, is he overly aggressive or does he stimulate memories of former abuse? What has been the partner's response to her pain? Does her pain actually start before penetration because of her dread of pain?

These example questions help the doctor and the patient get interested in the problem. A great deal has been learned about sexual pain disorders since the 1990s (Bergeron et al. 2003). Sex-limiting pain often is the result of the subtle interplay of personal and relational, cognitive and affective, and fundamental biological processes that are inherent in other human sexual struggles that operate to produce these confusing disorders (Binik 2005).

The DSM-IV-TR presents dyspareunia and vaginismus as distinct entities. However, they have been viewed as inextricably connected in much of the modern sexuality literature; vaginismus is known to create dyspareunia and dyspareunia has been known to create vaginismus.

**Dyspareunia**

Recurrent uncomfortable or painful intercourse in either gender is known as dyspareunia. Women's dyspareunia varies from discomfort at intromission, to severe unsparking pain during penile thrusting, to vaginal irritation following intercourse. In both sexes, recurring coital pain leads to inhibited arousal and sexual avoidance. “Dyspareunia” is used as both a symptom and a diagnosis. When coital pain is caused solely by defined physical pathology, dyspareunia due to a medical condition is diagnosed. When coital pain is due to vaginismus, insufficient lubrication, or other presumably psychogenic factors, dyspareunia not due to a medical condition diagnosis is made. Psychogenic etiologies may include a CNS pain perception problem raising the question, “What do we mean by psychogenic?”

**Psychogenic Sources of Dyspareunia**

Pain associated with intercourse may have purely subjective or psychological origin. Couple dynamics are often relevant, but the pain may be seen as a means of not allowing painful memories of childhood sexual abuse into clear focus. Fear of or helplessness about negotiating interpersonal conflicts may eventually lead to pain becoming a solution for avoiding unwanted sexual behaviors. While physicians tend to assume that pain has unconscious origins, sometimes it is merely faked; more often the patient is quite aware of its developmental origins but is too embarrassed to quickly communicate it to the doctor.

Personal psychological origins of painful intercourse pass through the common denominator of anxiety. Such anxiety may take the forms of dread of physical damage, worry about the psychological dependence that might result from physical union, fear of a first or another pregnancy,
The woman with lifelong vaginismus not only has a history of unsuccessful attempts at penetration but also displays an avoidance of orifice penetration. The most
dramatic aspect of her history, however, is her inability to endure a speculum examination of her vagina. Vaginismus is a phobia of vaginal entrance.

Treatment of Dyspareunia and Vaginismus

While vaginismus has the reputation of being readily treatable by gynecologists by pairing relaxation techniques with progressively larger vaginal dilators, the mental health professional typically approaches the problem differently (Bergeron et al. 2003). The psychiatric approach to both vaginismus and dyspareunia is attuned to the role that her symptom plays in her life. The therapy, therefore, does not begin with a cavalier, optimistic attempt to remove the symptom, which only frightens some patients. Rather, it begins with a patient exploration of the developmental and interpersonal meanings of the need for the symptom. “I wonder how this problem originally got started? Can you tell me a bit more about your life?” In the course of assisting women with these problems a variety of techniques may be utilized including relaxation techniques, sensate focus, dilatation, marital therapy, and medication. Short-term therapies should not be expected to have lasting good results because once the symptom is relieved, other problematic aspects of the patient’s sexual equilibrium and nonsexual relationship often come into focus. Clinicians have developed an impression that women with a diagnosis of dyspareunia are particularly difficult to help permanently. However, this is a largely unstudied topic.

Sexual Dysfunction Not Otherwise Specified

This diagnosis is reserved for circumstances that leave the doctor uncertain as to how to diagnose the patient. This may occur when the patient has too many fluctuating dysfunctional symptoms without a clear pattern of prominence of any one of them. Sometimes the psychiatrist is unable to determine whether the dysfunction is the basic complaint or when the sexual complaints are secondary to marital dysfunction. At other times the etiology is the uncertain: psychogenic, due to a general medical condition, or substance induced. When the patient does not emphasize the dysfunction as the problem but emphasizes instead the lack of emotional satisfaction from sex, the psychiatrist may temporarily provide this NOS diagnosis. It is usually possible to find a better dysfunction diagnosis after therapy begins.

GENDER IDENTITY DISORDERS

The organization of a stable gender identity is the first component of sexual identity to emerge during childhood. The processes that enable this accomplishment are so subtle that when a daughter consistently acts as though she realizes that “I am a girl and that is all right,” or when a son’s behavior makes a comparable announcement, families rarely even remember their children’s temporary confusion and behaviors to the contrary. Adolescent and adult gender concerns are not rare. They are, however, commonly hidden from a perceptive view, sometimes long enough to developmentally evolve into other less dramatic forms of sexual identity such as periodic cross-dressing, wish for hysterectomy, body dysmorphia. Gender identity variations provoke fascination, scorn, and controversy. Some transgendered adolescents and adults and scholars of sexual minority status argue that the concept of a gender identity disorder is based on a profound cultural misunderstanding and intolerance of variations in gender identity. They assert that parental anxiety that their gender variant child will grow up to be homosexual has stimulated psychiatry to endorse a hormonal/surgical treatment that falsely promises to restore the child to a simple male or female form (Hill et al. 2007). Others argue that treatment of gender identity disorder is humane relief of suffering, which makes patients happy, and has little to do with culturally widespread homophobia; gender identity and orientation are separate but often confused phenomena (Zucker 2004).

Extremely Feminine Young Boys

Although occasionally the parents of a feminine son have a convincing anecdote about persistent feminine interests dating from early in the second year of life, boyhood femininity is more typically only apparent by the third year. By the fourth year playmate preferences become obvious. Same-sex playmate preference is a typical characteristic of young children. Cross-gender–identified children consistently demonstrate the opposite-sex playmate preference (Maccoby and Jacklin 1987). The avoidance of other boys has serious consequences in terms of social rejection and loneliness throughout the school years. The peer problems of feminine boys cause some of their behavioral and emotional problems, which are in evidence by middle-to-late childhood (Zucker 1990). However, psychometric studies
support clinical impressions that feminine boys have emotional problems even before peer relationships become a factor; that is, something more basic about being cross-gender-identified creates problems. Young feminine boys have been shown to be depressed and have difficulties with separation anxiety (Coates and Person 1985).

Speculations about the origin of boyhood femininity generally suggest converging cumulative forces. Any child’s cross-gender identifications are likely to involve a host of factors: constitutional forces, problematic interactions with parents, problematic internal processing of life experiences, and family misfortune—financial, reproductive, physical disease, emotional illness, or death of vital persons. These factors are sometimes restated as temperament, disturbed family functioning, separation-individuation problems, and trauma.

Temperament is a dual phenomenon being both the child’s predisposition to respond to the world in a certain way and the aspects of the child to which others respond. The common temperamental factors of feminine boys have been described as follows: a sense of body fragility and vulnerability that leads to the avoidance of rough-and-tumble play; timidity and fearfulness in the face of new situations; a vulnerability to separation and loss; an unusual capacity for positive emotional connection to others; an ability to imitate; sensitivities to sound, color, texture, odor, temperature, and pain (Coates et al. 1992). This raises the issue whether some forms of this childhood disorder rest upon a more basic problem such as a pervasive developmental disorder. This matter of origin is often simplified by patients and professionals as “obviously biogenic,” which only avoids confronting the challenging psychopathophysiological mechanisms.

The development of boyhood femininity may occur within the mind of the toddler in response to a loss of emotional availability of a nurturing mother. The child creates a maternal (feminine) self through imitation and fantasy in order to make up for the mother’s emotional unavailability. This occurs beyond the family’s awareness and is left in place by the family either ignoring what has transpired in the son or valuing it. The problem for the feminine boy is that the social expectations of other people are unyielding; the adaptive early life solution becomes progressively more maladaptive with time. Only some children persist in their obstinate insistence of who they are in the face of increasing evidence to the contrary. The current answer to the question whether boyhood femininity is entirely constitutional, an adaptive solution that becomes maladaptive, or due to some other process is not known.

It is vital to remember that a large well-matched group of feminine boys were followed for over a decade. Undertaken to trace the evolution of early onset gender identity disorder, this study demonstrated that gender identity disorder did not persist; rather boyhood effeminacy was a frequent precursor of adolescent homosexuality and homosexual behavior (Green 1987). Feminine gender role behaviors give rise to more masculine behavioral styles as adolescence emerges.

**Masculine Girls: Tomboys**
The masculinity of girls may become apparent as early as age 2 years. The number of girls brought to clinical attention for cross-gendered behaviors, self-statements, and aspirations is consistently less than boys by a factor of 1:5 at an age of childhood in Western countries. This may reflect a difference in incidence of childhood gender disorders, negative cultural perceptions of femininity in boys, a broader range of cross-gender expression permitted to girls, or an intuitive understanding that cross-gender identity more accurately predicts homosexuality in boys than girls.

The distinction between tomboys and gender-disordered girls is often difficult to make. Tomboys are thought of as not as deeply unhappy about their femaleness, not as impossible to occasionally dress in stereotypic female clothing, and not thought to have as profound aversion to their womanly physiologic transformations. Tomboys are able to enjoy some feminine activities along with their obvious pleasures in masculine-identified activities. Girls who are diagnosed as gender disordered generally seem to have a relentless intensity about their masculine preoccupations and an insistence about their future. The onset of their cross-gendered identifications is early in life. Although most lesbians have a history of tomboyish behaviors, most tomboys develop a heterosexual orientation.

**The Subjectivity of a Well-Developed Gender Disorder**
Children, teenagers, and adults exist who rue the day they were born to their biological sex and who long for the opportunity to simply live their lives in a manner befitting the other gender. They repudiate the possibility of finding happiness within the broad framework of roles given to members of their sex by their society. Their repudiation seems to have nothing to do with social mores or political issues. They literally repudiate their gendered body, repudiate the self in that body, and reject performing roles expected of people with that body. They privately rebel against the need of others to designate them in terms of their biological sex.

The repudiation and rebellion may first occur as a subjective internal drama of fantasy, as behavioral expression in play, or a preference for the company of others. Regardless of when and how it is displayed, however, the drama involves the relentless feeling that “life would be better—easier, fuller, more enjoyable—if I and others could experience me as a member of the opposite sex.”

By mid-adolescence, the extremely gender disordered have often envisioned the solution for their paralyzing limiting self-consciousness: to live as a member of the opposite gender, to transform their bodies to the extent possible by modern medicine, and to be accepted by all others as the opposite sex. Some of them go beyond the fantasy or private cross-dressing and come to psychiatric attention. When a clinician is called in, the family has one set of hopes, the patient another. The clinician has many tasks, one of which is to mediate between the ambitions of the gender-disordered person and the family and see what can be done to help the patient. When these patients first appeared 50 years ago, most psychiatrists presumed they were psychotic. But actual evaluations revealed that the vast majority of patients’ sense of reality, apart from the gender issue, was not impaired. Even today, countertransference reactions can be quite aversive. Most patients self-refer or get referred to specialists in gender identity disorders, who, by and large, are not philosophically against sex/gender change. These therapists have discovered...
Gender Identity Disorder

A. A strong and persistent cross-gender identification (not merely a desire for any perceived cultural advantages of being the other sex). In children, the disturbance is manifested by four (or more) of the following:

1. Repeatedly stated desire to be, or insistence that he or she is, the other sex
2. In boys, preference for cross-dressing or simulating female attire; in girls, insistence on wearing only stereotypical masculine clothing
3. Strong and persistent preferences for cross-sex roles in make-believe play or persistent fantasies of being the other sex
4. Intense desire to participate in the stereotypical games and pastimes of the other sex
5. Strong preference for playmates of the other sex

In adolescents and adults, the disturbance is manifested by symptoms such as a stated desire to be the other sex, frequent passing as the other sex, desire to live or be treated as the other sex, or the conviction that he or she has the typical feelings and reactions of the other sex.

B. Persistent discomfort with his or her sex or sense of inappropriateness in the gender role of that sex.

In children, the disturbance is manifested by any of the following: in boys, assertion that his penis or testes are disgusting or will disappear or assertion that it would be better not to have a penis, or aversion toward rough-and-tumble play and rejection of male stereotypical toys, games, and activities; in girls, rejection of urinating in a sitting position, assertion that she has or will grow a penis, or assertion that she does not want to grow breasts or menstruate, or marked aversion toward normative feminine clothing.

In adolescents and adults, the disturbance is manifested by symptoms such as preoccupation with getting rid of primary and secondary sex characteristics (e.g., request for hormones, surgery, or other procedures to physically alter sexual characteristics to simulate the opposite sex) or belief that he or she was born the wrong sex.

C. The disturbance is not concurrent with a physical intersex condition.

D. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Code based on current age:

- 302.6 Gender identity disorder in children
- 302.85 Gender identity disorder in adolescents or adults

Specify (for sexually mature individuals):

- Sexually attracted to males
- Sexually attracted to females
- Sexually attracted to both
- Sexually attracted to neither

DSM-IV-TR Criteria

that these patients possess many of the ordinary aspects of life and one unusual ambition; they often want to be the opposite sex so badly that they are willing to make it a priority over family, friends, vocation, and material acquisition.

Diagnostic Criteria of Gender Identity Disorder

Adults who permanently change their bodies to deal with their gender dilemmas represent the far end of the spectrum of adaptations to gender problems. Even the lives of those who reject bodily change, however, have considerable pain because the images of a better gendered self may recur throughout life, becoming more powerful whenever life becomes strained or disappointing.

The diagnosis of the extreme end of the gender identity disorder spectrum is clinically obvious. The challenging diagnostic task for clinicians is to suspect gender struggles when a patient’s manner suggests a unisex or cross-gendered appearance, a dissociative identity disorder, severe forms of character pathology, and those who seem unusual based on a clinician’s intuition.

To qualify for gender identity disorder (GID), four criteria must be met.

Criterion 1: Strong, Persistent Cross-Gender Identification

Because young children may not verbalize enough about their inner experiences, for the clinician to be certain that this criterion is met, at least four of the five manifestations of cross-gender identification must be present: (1) repeatedly stated desire to be, or insistence that he or she is, the opposite sex; (2) in boys, preference for cross-dressing or simulating female attire; in girls, insistence on wearing stereotypical masculine clothing; (3) strong and persistent preferences for cross-gender roles in fantasy play or persistent fantasies of being the opposite sex; (4) intense desire to participate in the games and pastimes of the opposite sex; (5) strong preference for playmates of the opposite sex.
In adolescence and adulthood, this criterion is fulfilled when the patient states the desire to be the opposite sex, has frequent social forays into appearing as the opposite sex, desires to live or be treated as the opposite sex, or has the conviction that his or her feelings and reactions are those typical of the opposite sex.

**Criterion 2: Persistent Discomfort with One’s Gender or the Sense of Inappropriateness in a Gender Role**

This criterion is fulfilled in boys who assert that their penis or testicles are disgusting or will disappear or that it would be better not to have these organs; or who demonstrate an aversion toward rough-and-tumble play and rejection of male stereotypical toys, games, and activities. In girls, rejection of urinating in a sitting position or assertion that they do not want to grow breasts or menstruate, or marked aversion toward normative feminine clothing fulfill this criterion.

Among adolescents and adults, this criterion is fulfilled by the patient’s exhibiting the following characteristics: preoccupation with getting rid of primary and secondary sex characteristics; preoccupation with thoughts about hormones, surgery, or other alterations of the body to enhance the capacity to pass as a member of the opposite sex such as electrolysis for beard removal, cricoid cartilage shave to minimize the Adam’s apple, breast augmentation; or preoccupation with the belief that one was born into the wrong sex.

**Criterion 3: Not Due to an Intersex Condition**

In the vast majority of clinical circumstances, the patient possesses normal genital anatomy and sexual physiology. When a patient with a GID and an accompanying intersex condition such as congenital adrenal hyperplasia, an anomaly of the genitalia, or a chromosomal abnormality is encountered, the clinician will be uncertain whether the intersex condition is the cause of the GID because the vast majority of patients with intersex conditions do not meet criteria for GID (Diamond and Watson 2004). The clinician may either diagnose gender identity disorder not otherwise specified (GIDNOS) or list GID on Axis I and the intersex condition on Axis III.

**Criterion 4: Significant Distress and Impairment**

It is likely that many children, adolescents, and adults struggle for a while to consolidate their gender identity but eventually find an adaptation that does not impair their capacities to function socially, academically, or vocationally as a member of their sex. These persons do not qualify for GID nor do those who simply are not stereotypic in how they portray their gender roles. Mental health professionals encounter parents who are disturbed by their adolescent child’s gender roles. Parental distress is not the point of criterion 4; this criterion refers to patient distress.

**Diagnostic Criteria of GIDNOS**

If an accurate community-based study of the gender-impaired could be conducted, most cases would be diagnosed as GIDNOS. The diagnostician needs to understand that gender identity development is a dynamic evolutionary process and clinicians get to see people at crisis points in their lives. At any given time, although it is clear that the patient has some form of GID, it may not be that which is described as GID. Here is one example: an adult female calls herself a “neuter.” She wants her breasts removed because she hates to be perceived as a woman. For 2 years she has been exploring “neuterdom” and states that “I am definitely not interested in being a man!” She may be classified as GIDNOS.

GIDNOS is a large category designed to be inclusive of those with unusual genders who do not clearly fit the criteria of GID. There is no implication that if a patient is labeled GIDNOS his or her label cannot change. GIDNOS contains the many forms of transvestism: masculine-appearing boys and teenagers with persistent cross-dressing (former fetishistic transvestites) who are evolving toward GID; socially isolated men who want to become a woman shortly after their wives or mothers die (secondary transvestites) but express considerable ambivalence about the very matter they passionately desired at their last visit, extremely feminized homosexuals with careers as “drag queens” who seem to want to change their sex when depressed, and so on. GIDNOS would also capture men who want to be rid of their genitals without being feminized, unisexual females who imagine themselves as males but who are terrified of any social expression of their masculine gender identity, masculine lesbians in periodic turmoil over their gender, and those women who strongly identify with both male and female who want mastectomies. In using gender identity diagnoses, clinicians need to be mindful that the Axis I diagnosis is focused on gender identity/role not orientation. To dismiss a patient as merely homosexual is to not grasp the primacy of the patient’s developmental problem.

Some patients with struggles over gender expression would not be either GID or GIDNOS. Some would diagnose this man as having a paraphilia.
Clinical Vignette 3 continued

that nothing, including his fundamentalist religious patterns, diminished his periodic need to wear women's clothing. “If I tell her about my cross-dressing, she withdraws in anger. If I do not tell her about it, her imagination about how often I am doing it runs wild and she punishes me for cross-dressing that I don’t do. If I stop cross-dressing, I deprive myself of unparalleled comfort and sumptuous pleasure and the desire eventually overtakes me. I lose either way. Should I honor my wife or my own identity?” His daily rate of masturbation has not changed much. He thinks he masturbates to cope with her refusal to have sexual behavior together. “My cross-dressing has actually kept me from having affairs with other women, thankfully.”

Three factors point to the paraphilia Fetishistic Transvestism as a diagnosis: his arousal to female clothing was reported to have increased over time, he cross-dresses without a well-developed feminine identity, and he masturbates daily. Let us now add to this description his wife’s new diagnoses of advanced ovarian cancer. As he copes with this bad news and helps her with the painful process of dying, within his privacy is stirring his need to increase his social presentation as a woman, his fantasies of having genital reconstruction, and his recognition that his grief is balanced by his opportunity to live as a woman soon. If the psychiatrist sees him after his wife’s death, GIDNOS might appear to be the new diagnosis. Fetishistic Transvestism, GIDNOS, and GID can be evolutionary points in a person’s life.

The Relationship of GIDs to Orientation

The usual clarity of distinctions between heterosexual, bisexual, and homosexual orientations rests upon the assumption that the biological sex and psychological gender of the person and the partner are known. A woman who designates herself as a lesbian is understood to mean she is erotically attracted to other women. “Lesbian” loses its meaning if the woman says she feels she is a man and lives as one. She insists, “I am a heterosexual man; men are attracted to women as am I!” The clinician may erroneously think, “You are a female therefore you are a lesbian!” DSM-IV-TR suggests that adults with GID should be grouped according to which sex the patient is currently assigned to, and how they think about their gender. People who have lived for a long time with a different identity disorder or gender identity disorder NOS but effort should be made to assess whether another treatable psychiatric or physical disorder is present.

Treatment Options for the GIDs

The treatment of these conditions, although not as based on rigorous scientific evidence, is scrutinized by multidisciplinary committees of specialists within the World Professional Association for Transgendered Health who periodically update their Standards of Care (Meyer et al. 2001). The treatment of any GID begins after a careful evaluation, including interviews with parents, other family members and spouses, psychometric testing, and occasionally physical and laboratory examination. The details will depend on the age of the patient. It is possible, of course, to have a GID as well as mental retardation, a psychosis, dysthymic disorder, severe character pathology, or any other psychiatric diagnosis (Table 77–8).

Table 77–8 Steps in Evaluation of the Profoundly Gender Disordered*

<th>Steps in Evaluation of the Profoundly Gender Disordered*</th>
</tr>
</thead>
<tbody>
<tr>
<td>Step One</td>
<td>Formal evaluation and diagnosis leads to either gender identity disorder or gender identity disorder NOS but effort should be made to assess whether another treatable psychiatric or physical disorder is present.</td>
</tr>
<tr>
<td>Step Two</td>
<td>Referral of patient for individual psychotherapy within the gender program or with an interested professional. Do the diagnoses remain the same? If yes, does the patient consistently want to: Discuss his (or her) situation but make no changes? Increase cross-dressing toward cross-living? Prepare the family for the real-life test? Obtain permission to proceed with hormones?</td>
</tr>
<tr>
<td>Step Three</td>
<td>Approval for hormones from a gender committee or on written recommendation from the psychiatrist to an endocrinologist. Individual or group psychotherapy should continue.</td>
</tr>
<tr>
<td>Step Four</td>
<td>Real-life test of living and working full time in the aspired-to-gender role for at least 1 year. Does the patient want to continue to surgery?</td>
</tr>
<tr>
<td>Step Five</td>
<td>Gender committee approval for surgery. Many patients have cosmetic surgery other than that listed with only ordinary patient–surgeon consent. This most often involves breast augmentation but may include numerous other attempts to improve ability to pass as opposite sex and be attractive.</td>
</tr>
</tbody>
</table>

| Men: genital reconstruction |
| Women: mastectomy, hysterectomy, genital reconstruction |

*Most patients will not complete all of these steps

Individual Psychotherapy

There is no psychotherapy technique to cure an adult’s gender problem. People who have long lived with profound cross-gender identifications do not simply obtain insight, get behaviorally modified, or get medicated into a conventional gender identity. Psychotherapy can be useful, nonetheless. If the patient is able to trust a therapist, there can be much to talk about—family relationships are often painful, barriers to relationship intimacy are profound, work poses many difficult issues, and there is the matter of psychic reality. Perhaps gender change does not erase the psychic remnants of past history and characterologic features. Perhaps when the surgery is accomplished, loneliness will continue; particularly if family has been abandoned. What happens if the transsexual past causes others to avoid the patient? The patient naturally thinks about “How am I going to live my life if I don’t go through with cross-gender living, hormone therapy, mastectomy, or genital surgery and if I do?” The therapist can help the patient recognize and respect previously unstated ambivalence. Completion of the gender transformation process usually takes longer than the patient
Group Therapy

Group therapy for gender-disordered people has the advantages of allowing patients to know others with gender problems, of decreasing their social isolation, and of being among people who do not experience their cross-gender preoccupations and their past behaviors as weird. Group members can provide help with grooming and more convincing public appearances. The success of these groups depends on the therapist’s skills. In recent years, the groups have morphed into self-help groups without a therapist.

“Real-Life Experience or Test”

Living in the aspired-to-gender role—working, relating, conducting the activities of daily living—is a vital process that enables one of three decisions to be made: to abandon the quest, to simply live in this new role, or to proceed with breast or genital surgery (Petersen and Dickey 1995). Some clinicians use the real-life test as a criterion for recommending hormones but this varies because some patients’ abilities to present themselves in a new way are definitely enhanced by prior administration of cross-sex hormones. The reason for the real-life experience is to give the patient, who created a transsexual solution in fantasy, an opportunity to experience the solution in reality. The real-life experience should improve the patient’s psychological function. If it does not, the clinician and patient have to be wary of gender transition.

Hormone Therapy

Ideally, hormones should be administered by endocrinologists who have a working relationship with a mental health team dealing with gender problems. The effects of administration of estrogen to a biological male are as follows: breast development, testicular atrophy, decreased sexual drive, decreased semen volume and fertility, softening of skin, fat redistribution in a female pattern, and decrease in spontaneous erections. Breast development is often the highest concern to the patient. Because hair growth is not affected by estrogens, electrolysis or laser treatments are used to remove beard growth. Side effects within recommended doses include hypertension, hyperglycemia, lipid abnormalities, thrombophlebitis, and hepatic dysfunction. Patients should therefore be monitored regularly. The most dramatic effect of hormones is on the sense of well-being, which is so quickly apparent through patients’ reports of feeling calmer and happier knowing that their bodies are being demasculinized and feminized that clinicians have wondered what a placebo-controlled study might demonstrate.

The administration of androgen to females results in an increased sexual drive, clitoral tingling and growth, weight gain, and amenorrhea and hoarseness. An increase in muscle mass may be apparent if weight training is undertaken simultaneously. Hair growth depends on the patient’s genetic potential. Androgens are administrated intramuscularly 200–300 mg/month. It is prudent to periodically monitor hepatic, lipid, and thyroid functioning. Most patients are delighted with their bodily changes. Breast size does not significantly regress on androgens.

Surgical Therapy

Surgical intervention is the final external step. It should not occur without a mental health professional’s input, even when the patient provides a heart-felt convincing set of reasons to bypass the real-life test, hormones, and psychotherapy. Genital surgery is expensive, time-consuming, at times painful, and has frequent anatomic complications and functional disappointments. Surgery has the potential to add further improvements in the lives of patients—more social activities with friends and family, more activity in sports, more partner sexual activity, and improved vocational status (Mate-Kole et al. 1990). Thousands of patients worldwide have received surgery. Following them systematically over time to ascertain their short-, medium-, and long-term adjustments have proven elusive, however. Nonetheless, there are specialists who are quite positive (Pfafflin 2003) and those who are more skeptical (Carroll 1999).

Males

Surgery consists of penectomy, orchiectomy, vaginoplasty, and fashioning of labia. The procedures used for the creation of a neovagina have evolved over the years. Postoperatively, the patient must maintain the patency of the neovagina by initially constantly wearing and then periodically using a vaginal dilator. Vaginal stenosis or shortening is a frequent complication. The quest for an unmistakable feminine shape leads many young adult patients to augmentation mammoplasty and the shaving of the cricoid cartilage.

Females

The creation of a male-appearing chest through mastectomies and contouring of the chest wall requires only a brief hospital stay. Patients are usually immediately delighted with their newfound freedom, but their fantasies of going shirtless are often not fulfilled due to the presence of two noticeable horizontal chest scars. The creation of a neophallus that
can become erect, contain a functional urethra throughout its length (enabling urination while standing), and pass as an unremarkable penis in a locker room has been a significant surgical challenge and is far from being perfected. The surgery is, however, the most time-consuming, technically difficult, and expensive of all the sex reassignment procedures. Erection is made possible by a penile prosthesis. Many prudent patients consider themselves reassigned when they have a hysterectomy, oophorectomy, and mastectomy. Some just have a mastectomy. They find a partner who understands the situation and supports the idea of living with, and loving with, female genitals.

Ongoing controversy about sex reassignment surgery is ultimately based on the overarching principle of medical ethics, “Above all, do not harm.” The removal of healthy tissue, which GID specialists argue helps rather than harms the patient, creates a distinct countertransference avoidance of working with this community of patients. Negative countertransference needs to be recognized and its roots appreciated by both sides in the endless controversy about how to care for people who entertain bodily transformations for their distress over gender.

THE PARAPHILIAS

A paraphilia is a disorder of intention, the final component of sexual identity to develop in children and adolescents. Intention refers to what individuals want to do with a sexual partner and what they want the partner to do with them during sexual behavior. Normally, the images and the behaviors of intention are characterized by peaceful mutuality. The disorders of intention are recognized by unusual eroticism (images) and often socially destructive behaviors such as sex with children, rape, exhibitionism, voyeurism, masochism, obscene phone calling, or sexual touching of strangers. Only about 5% of the diagnoses of paraphilia are given to women raising the question whether there are unrecognized forms of female paraphilia (Beier 2000). All etiologic speculations of paraphilia try to explain how male sexual development has gone awry. Accounts of paraphilic behaviors have been in general literatures for centuries, but they have been of psychiatric interest only since 1905 (Freud 1905). Freud thought of the paraphilias as deprivations in the aim of the sexual instinct. He coined the term by combining the Greek words for “along the side” (para) and “love” (philias). In 1905, paraphilia denoted those fixed preferences for sexual behaviors that led to forms of orgasmic attainment other than the uniting of penis and vagina.

Now it is apparent that paraphilias occur among individuals of all orientations and among those with conventional and unconventional gender identities. A homosexual sadist is paraphilic only on the basis of sexual cruelty. A transsexual who desires to be beaten during arousal is paraphilic only on the basis of masochism.

Three General Characteristics of the Paraphilias

A Long-standing, Unusual, Highly Arousing Erotic Preoccupation

Erotic intentions that are recent in origin, conventional, and somewhat exciting may be problematic in some way but they are typically not clearly paraphilic. The sine qua non of the diagnosis of paraphilia is unusual, often hostile or demeaning dehumanized eroticism, which has preoccupied the patient for most of his adolescent and adult life. The paraphilic fantasy is often associated with this preoccupying arousal when it occurs in daydreams and masturbation reveries or is encountered in explicit films or magazines. The specific imagery varies from one paraphilic patient to the next, but both the imagined behavior and its implied relationship to the partner are unusual. This often means that it is suffused with overt or subtle forms of aggression such as the wish to hurt a child the way he was hurt when he was at a particular age. Paraphilias may be unusual also in that the focus is not actually about a partner—it is about an inanimate thing such as clothing or about the image of the self as a woman. Images of rape, obscene phone calling, exhibitionism, and touching of strangers are rehearsals of victimization. In masochistic images, the aggression is directed at the self; for instance, autoerotic strangulation, slavery, torture, spanking. In others, the aggression is well disguised as love of children or teenagers. In some, however, aggression is absent. Aggression is so apparent in most paraphilic content, however, that when none seems to exist, the clinician needs to wonder whether it is actually absent or being hidden from the doctor. Paraphilic fantasies often rely heavily upon the image of a partner who does not possess “personhood.” Some imagery in fact has no pretense of a human partner at all; clothing, animals, or excretory products are the focus. Other themes such as preoccupation with feet or hair combine both human and inanimate interests. Paraphilic images are usually devoid of any pretense of caring or human attachment. The hatred, anger, fear, vengeance, or worthlessness expressed in them requires no familiarity with the partner. Paraphilic images are conscious—clearly known to the individual. They should not be confused with speculations about “unconscious” aggression or sadomasochism that some assume are part of all sexual behavior. Clinicians should expect to occasionally see paraphilic patients whose preoccupations are not hostile to others.

An individual’s paraphilic themes often change in intensity or seem to change in content from time to time. The stimuli for these changes often remain unclear. It is a moot point whether such changes should be considered a shift to a different disorder, a new paraphilia, or a natural evolution of the basic problem. The shifts from imagining talking “dirty” on the phone in order to scare a woman to imagining raping can be considered an intensification of sadism. Switches between sadism and masochism or voyeurism and exhibitionism are common. Changes from voyeurism to pedophilia or from pedophilia to rape, however, raise the question whether a new disorder has developed. The most socially significant shifts are from erotic imagery to sexual behavior. In most instances, it is reasonable to consider that paraphilia is a basic developmental disorder in which particular erotic and sexual manifestations are shaped by the individuality of the person’s history.

Most paraphilic adults can trace their fantasy themes to puberty and many can remember these images from earlier years. When adolescent rapists or incest offenders are evaluated, they often are able to report prepubertal aggressive erotic preoccupations. Men who report periodic paraphilic imagery interspersed with more usual eroticism.
have had their paraphilic themes from childhood or early adolescence. To make a diagnosis of paraphilia, the patient must evidence at least 6 months of the unusual erotic preoccupation. Duration is usually not in question, even among adolescents, however (Shaw 1999).

**Pressure to Act Out the Fantasy**

To be paraphilic often means that the erotic imagery exerts a pressure to play out the often imagined scene. In its milder forms, the pressure results merely in a preoccupation with a behavior. For instance, a man who prefers to be spoken to harshly and dominated by his wife during sex thinks about his masochistic images primarily around their sexual behaviors. He does not spend hours daydreaming of his erotic preferences. In its more intense forms, paraphiliacs create a *drive* sens to act out the fantasy in sexual behavior—usually in masturbation while wearing panty hose, tying a ligature around his neck, or inserting a dildo into the rectum while spanning himself. Frequent masturbation, often more than once daily, continues long after adolescence and generally exceeds the rate found in most men his age. In the most severe situations, the need to attend to the fantasy and masturbate is so overpowering that life’s ordinary activities cannot efficiently occur. Masturbation and sometimes partner-seeking behavior—such as finding a woman to shock through exhibiting an erection—is experienced as driven. The patient reports either that he cannot control his behavior or he controls it with such great effort that his work, study, parenting, and relationships are disrupted. This pressure to behave sexually often leads the man to believe he has a high sex drive. Some severe paraphiliacs describe their masturbation-to-orgasm frequencies as 10/day. Even when the patient’s estimate of his frequency of orgasm strains credulity less, the return of sexual drive manifestations so soon after orgasm (Kafka 2000) suggests that either something is wrong with the patients’ sexual drive generator, their satiety mechanisms, or that their existential anxiety overpowers their other defense mechanisms.

Paraphilic men often report collecting and viewing pornography, visiting sexual bookstores to see explicit videos or peep shows, frequenting prostitutes for their special sexual behaviors, downloading explicit images from the Internet, or extensively using telephone sex services or strip clubs. Victimization of others, while certainly a serious problem, is the least common form of sexual actuations that women had penises and that men could lose theirs during sex (castration anxiety); (5) the unsuccessful repair of early life passive, helpless experiences with a terrifying, malignant, malicious preoedipal mother; (6) a strategy to stabilize a conventional masculine or feminine gender identity; (7) a strategy to deny the differences between the sexes and the generations of child and parent; (8) an outcome of childhood sexual abuse; (9) a consequence of far less than ideal parent–child relationships; (10) a soft neurological sign of a neural wiring defect; (11) a released behavior due to cerebral pathology—for example, temporal lobe dysfunction, or substance abuse; (12) the sexual face of an addiction disorder; (13) an unusual manifestation of an addictive disorder; (14) an obsesive–compulsive spectrum disorder; (15) a defective self-system requiring a patch—that is, a sexual preoccupation—to shore up the private, carefully-hidden-from-others sense of inadequate subjective masculinity.

Whatever its ultimate psychopathogenesis and nature, the paraphiliacs are sexual identity disorders that generally make normal erotic and sexual loving unattainable. Culture asks us to have some image of attachment, some ability to neutralize anger toward others, some ability to contain the anxiety over closeness, and some psychological motive to simultaneously enhance the self and the partner through sexual contact. Ordinary intentions aim for peaceable mutuality between real people; paraphilic ones aim at aggressive one-sidedness. Impaired masculinity is another phrase that conveys a persistent subjective sense of sexual identity. Some paraphilic men will acknowledge that they do not feel entirely masculine or that their paraphilic activities bolster their sense of masculinity. “I am far more reliably potent when I cross-dress... hurt a woman... think of myself as a woman receiving a penis in my vagina, etc.” This sexual identity disorder could be referred to as a disorder of self, specifically of that part of the self that maintains a sense of masculinity. Paraphilics often bear an enigmatic paradox between what they want to be and what they are. They often hunger for a behavior that feels sick or uncontrollable and that robs them of autonomy. This is why the behaviors are often thought of as addictions and are often associated with other forms of substance abuse, obsessive–compulsive phenomena, and affective symptoms. Relative to the dynamic

**Partner Sexual Dysfunction**

A sexual dysfunction involving desire, arousal, or orgasm with a partner, although not invariably present among paraphiliacs, is common. The wives of paraphiliacs tell stories with these themes: “He is not interested in sex with me.” “He never initiates.” “He doesn’t seem to enjoy our sexual life together except when...” “He is usually not potent.” “Even when we do make love, he rarely ejaculates.” Some paraphilic men, however, are able to function well without paraphilic fantasies but others are either able to primarily function when their partners are willing to meet their special requirements for arousal or when they fantasize about their paraphilic script.

**Speculations About the Underlying Problem**

Paraphilia has been considered in 15 somewhat different ways, depending on era, ideology, and region: (1) an impairment in the bonding function of sexuality; (2) a courtship disorder; (3) the erotic form of hatred motivated by the need for revenge for childhood trauma; (4) a fixation to childhood misunderstandings that women had penises and that men could lose theirs during sex (castration anxiety); (5) the unsuccessful repair of early life passive, helpless experiences with a terrifying, malignant, malicious preoedipal mother; (6) a strategy to stabilize a conventional masculine or feminine gender identity; (7) a strategy to deny the differences between the sexes and the generations of child and parent; (8) an outcome of childhood sexual abuse; (9) a consequence of far less than ideal parent–child relationships; (10) a soft neurological sign of a neural wiring defect; (11) a released behavior due to cerebral pathology—for example, temporal lobe dysfunction, or substance abuse; (12) the sexual face of an addiction disorder; (13) an unusual manifestation of an addictive disorder; (14) an obsesive–compulsive spectrum disorder; (15) a defective self-system requiring a patch—that is, a sexual preoccupation—to shore up the private, carefully-hidden-from-others sense of inadequate subjective masculinity.
fluctuations of sexual dysfunctions, intention disorders are tenacious throughout life.

Classic studies of psychiatric epidemiology have never investigated the prevalence of paraphilia. The rise of the Internet, which provides something for every erotic taste, has also helped some men to discover their intense excitement over images that they previously only dimly imagined. Thus, the Internet may subtly increase the prevalence of paraphilic eroticism.

**The Specific Paraphilias**

**Criminal Sex Offending Behaviors**

**Exhibitionism**

Exhibitionism generally involves teenagers and men displaying their penises so that the witness will be shocked or (in the paraphilic’s fantasy) sexually interested. They may or may not masturbate during or immediately following this act of victimization. This diagnosis is not usually made when a man is arrested for “public indecency” and his penile exposures are motivated to arrange homosexual contact in a public place generally unseen by heterosexuals. Penile display in parks is one way to make anonymous contact. The presence or absence of exhibitionistic imagery allows the clinician to make the distinction between paraphilia and homosexual courting. Clinicians should not assume that men with homosexual orientations cannot suffer from exhibitionism.

---

**Clinical Vignette 4**

A 43-year-old married policeman was incarcerated after evidence linked him to six rapes. Five years prior to his arrest, he described to his psychotherapist the adolescent beginning of a lifelong erotic form of stalking. He masturbated to images of following woman years before he began to incorporate rape into the scenario. He spent much of his leisure time selecting women visually, finding out about them, and following them. The vast majority of his “victims” were never aware of his stalking behaviors, but these behaviors fueled his more than daily masturbation. He claimed and his wife confirmed that for most of their marriage he had no apparent sexual interest in her. Superficially, he was a stalker, but the aim of stalking was sadistic dominance, fear-inducing rape.

---

**Pedophilia**

Pedophilia is the most widely and intensely socially repudiated of the paraphilias. Pedophiles are men who erotically and romantically prefer children or prepubertal adolescents. They are grouped into categories depending upon their erotic preferences for boys or girls and for infant, young, or pubertal children. There is some confusion between when a prepubertal child is an adolescent. Society, though not the DSM-IV-TR, thinks of a pedophile as a person who sexually targets a minor and therefore prosecutes under this term adults who target adolescents. Some pedophiles have highly age- and sex-specific tastes, others are less discriminating. Since the diagnosis of any paraphilia including pedophilia requires recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children over a period of at least 6 months, the disorder should not be expected to be present in every person who is guilty of child molestation. Some intrafamilial child abuse occurs over a shorter time interval and results from combinations of deteriorated marriages, sexual deprivation, sociopathy, and substance abuse. Child molestation, whether paraphilic or not, is a crime, however. Child molesters show several patterns of erectile responses to visual stimulation in the laboratory. Some have their largest arousal to children of a specific age and others respond to both children and adults (Marshall et al. 2006). These tests, however, cannot alone be relied upon for the diagnosis. Some recognized that pedophiles can pass phalometric and visual response time examinations—that is, appear to be interested in only adolescents and adults. (The ordinary heterosexual responds both to adolescents and adults.) Some pedophiles respond with their greatest arousal to aggressive cues.

**Voyeurism**

Men whose sexual life consists of watching homosexual or heterosexual videos in sexual bookstores occasionally come to psychiatric attention after being charged with a crime following a police raid. The voyeurs who are more problematic for society are those who watch women through windows or break into their dwellings for this purpose. Some of these crimes result in rape or nonsexual violence, but many are motivated by pure voyeuristic intent (which is subtly aggressive).

---

**DSM-IV-TR Criteria**

**Voyeurism**

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the act of observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity.

B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Pedophiles are grouped into categories depending upon their erotic preferences for boys or girls and for infant, young, or pubertal children. There is some confusion between when a prepubertal child is an adolescent. Society, though not the DSM-IV-TR, thinks of a pedophile as a person who sexually targets a minor and therefore prosecutes under this term adults who target adolescents. Some pedophiles have highly age- and sex-specific tastes, others are less discriminating. Since the diagnosis of any paraphilia including pedophilia requires recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children over a period of at least 6 months, the disorder should not be expected to be present in every person who is guilty of child molestation. These tests, however, cannot alone be relied upon for the diagnosis. Some recognized that pedophiles can pass phalometric and visual response time examinations—that is, appear to be interested in only adolescents and adults. (The ordinary heterosexual responds both to adolescents and adults.) Some pedophiles respond with their greatest arousal to aggressive cues.

---

**Sexual Sadism**

While rape is an extreme variety of sadism, paraphilic sadism is present only in a minority of rapists. It is defined by the rapist’s prior use of erotic scripts that involve a partner’s fear, pain, humiliation, and suffering. Rapists, whether paraphilic or not, are highly dangerous men whose antisocial behaviors are generally thought to be unresponsive to ordinary psychiatric methods. Their violence poten-
often are unaware of how frightening they can be. Isolated men who become sexually driven to act out. They may represent persons, although delineated as a criminal act, is probably better understood as the most socially benign form of paraphilic sadism. Frotteurism often occurs in socially isolated men who become sexually driven to act out. They are unaware of how frightening they can be.

**Frotteurism**

Frotteurism, the need to touch and rub against nonconsenting persons, although delineated as a criminal act, is probably better understood as the most socially benign form of paraphilic sadism. Frotteurism often occurs in socially isolated men who become sexually driven to act out. They are unaware of how frightening they can be.

**DSM-IV-TR Criteria**

**Sexual Sadism**

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving acts (real, not simulated) in which the psychological or physical suffering (including humiliation) of the victim is sexually exciting to the person.

B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**Stalking**

Stalking is the latest erotic preoccupation to be criminalized. Forensic psychiatry has defined various motivations for arrested stalkers, including those who have made the transition from romantic to violent preoccupation with the victim. Stalking is particularly frightening because murder occasionally results. It is likely that stalking as a behavior is the product of further deterioration of an already compromised mind, although not necessarily a paraphilic one. Some stalkers are found to be sexual sadists.

**DSM-IV-TR Criteria**

**Frotteurism**

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving touching and rubbing against a nonconsenting person.

B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
Fetishism

Garment for decades is classified as a paraphilia, but many overlap with GIDNOS. Transvestic fetishism is the diagnosis cases involve more complex varieties of cross-dressing and arousal purposes. Fetishism when confined to one garment for decades is classified as a paraphilia, but many cases involve more complex varieties of cross-dressing and overlap with GIDNOS. Transvestic fetishism is the diagnosis used when it is apparent that the urges to use the clothing of the opposite sex is part of a larger mental preoccupation with that sex.

Sexual Masochism

Sexual masochism is diagnosed over a range of behaviors from the sometimes fatal need to nearly asphyxiate oneself.

Noncriminal Forms of Paraphilia

Because the individual manifestations of paraphilia depend on the particular individual life history of the affected, over 150 paraphilic categories have been identified. Most fall into variations of those listed in the DSM-IV-TR but there are relatively rare exceptions. All convey an unusual means of achieving arousal during masturbation or consenting partner behaviors. They range widely from the bizarre to the more “reasonable” and from the common to the unique. They often subtly combine elements of more than one paraphilia.

Fetishism

Fetishism, the pairing of arousal with wearing or holding an article of clothing or inanimate object such as an inflatable doll, has a range of manifestations from infantilism in which a person dresses up in diapers to pretend he is a baby to the far more common use of a female undergarment for arousal purposes. Fetishism when confined to one garment for decades is classified as a paraphilia, but many cases involve more complex varieties of cross-dressing and overlap with GIDNOS. Transvestic fetishism is the diagnosis used when it is apparent that the urges to use the clothing of the opposite sex is part of a larger mental preoccupation with that sex.

DSM-IV-TR Criteria

Fetishism

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the use of nonliving objects (e.g., female undergarments).

B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The fetish objects are not limited to articles of female clothing used in cross-dressing (as in transvestic fetishism) or devices designed for the purpose of tactile genital stimulation (e.g., a vibrator).

Paraphilia Not Otherwise Specified

Paraphilia not otherwise specified is a DSM-IV-TR category for other endpoints of abnormal sexual development that lead to preoccupations with other paraphilic stimuli, including amputees, feces, urine, sexualized enemas, sex with animals, sex with the dead, etc.

Treatment

Four general approaches are employed to treat the paraphilias. The treatments are typically multimodal in application (Marshall et al. 2006).
Psychotherapy that have triggered acting out. Treatment techniques often involve attempting to interrupt paraphilic arousal via pairing masturbatory excitement with either aversive imagery or aversive stimuli, social skills training, assertiveness training, and confrontation with the rationalizations that are used to minimize awareness of the victims of sexual crimes, and marital therapy (Abel and Osborn 1995). The self-help movement has created 12-step programs for sexual addictions to which many individuals now belong. Group psychotherapy is offered by trained therapists as well. When the lives of paraphilics are illuminated in various therapies, it becomes apparent that the emotional pain of the patients is thought to be great; the sexual acting out is often perceived as a defense against recurrent unpleasant emotions from any source. These often, however, involve self-esteem and attachment anxiety or anxiety over closeness.

**Medications**

In the early 1980s, depo-medroxy-progesterone (Provera) was first used to treat those who were constantly masturbating, seeking out personally dangerous sexual outlets, or committing sex crimes. The weekly 400–600 mg injections often led to the men being able to work, study, or participate in activities that were previously beyond them because of concentration or attention difficulties. In the late 1980s, the use of oral Provera, 20–120 mg/day led to similar results: the drug enabled these men to leave their former state in which their sexual needs took priority over other life demands, and they did not have depo-Provera’s side effect profile—weight gain, hypertension, muscle cramps, and gynecomastia. Today, gonadotrophin-releasing blockers such as leuprolide acetate (Lupron) are occasionally used for this purpose (Kreuger and Kaplan 2001). The possible side effects are similar to oral Provera. Despite the fact that the clinical results are among the most powerfully effected by any psychopharmacologic treatment, many psychiatrists cannot overcome their disinclination to give a “female” hormone to a man or to work with patients who victimize others sexually. Serotonergic agents are now more commonly used as a first line of treatment and their administration, of course, creates fewer countertransference obstacles. While these studies are the result of open labeled series of cases without placebo control groups, the SSRIs are in widespread use for compulsive sexual behaviors and sexual obsessions. Their efficacy is the source of the speculation that some of the paraphilias may be an obsessive–compulsive spectrum disorder.

**External Controls**

Sexual advantage-taking, whether it be by a paraphilic physician with his patients, by a pedophilic mentally retarded man in the neighborhood, or of a grandfather who has abused several generations of his offspring, can often be stopped by making it impossible for these behaviors to be unknown to most people in his life. The doctor’s staff can be told, the neighbors can know, the family can meet to discuss the current crisis and review who has been abused over the years and plan to never allow grandfather alone with any child in or outside the family. The concept of external control is taken over by the judicial system when sex crimes are highly repugnant or heinous. The offender is removed from society for punishment and the protection of the public. This includes physicians who have sexually abused patients.
Psychiatrists need to be realistic about the limitations of various therapeutic ventures. Sexual acting out may readily continue during therapy beyond the awareness of the therapist. The more violent and destructive the paraphilic behavior is to others, the less the therapist should risk ambulatory treatment. Unfortunately, outside of a few forensic mental hospitals and occasion prisons, there are limited inpatient treatment program for sex offenders, paraphilic or not. Since paraphilia occurs in patients with other psychiatric conditions, the psychiatrist needs to remain vigilant that the treatment program is comprehensive and does not lose sight of the paraphilia just because the depressive or obsessive–compulsive symptoms are improved. Paraphilia may be improved by medications and psychotherapy but the clinician should expect that the intention disorder is the patient's lasting vulnerability.

**SEXUAL DISORDER NOT OTHERWISE SPECIFIED**

If the clinician is uncertain about how to categorize a person's problem, it is more reasonable to use this diagnosis than one that does not encompass the range of the patient's suffering. Sexual disorder not otherwise specified can be used when the therapist perceives a dramatic interplay between issues of sexual identity and sexual dysfunction, or when “everything” seems to be amiss. DSM-IV-TR, however, encourages the clinician to make multiple sexual diagnoses involving, for instance, a GID, a desire disorder, erectile, and orgasmic disorder.

DSM-IV-TR provides three examples when it would be appropriate to use the diagnosis sexual disorder NOS: (1) nonparaphilic compulsive sexual behaviors—that is, relentless pursuit of masturbatory or heterosexual or homosexual partner experiences without evidence of paraphilic imagery; (2) distress about a pattern of repeated sexual relationships involving a succession of lovers who are experienced by the individual only as things to be used; (3) persistent and marked distress about sexual orientation. Despite the removal of homosexuality from the DSM in 1974, men (particularly) and women still generate symptoms in their struggle to balance the demands of their homoeoticism with their ambitions to participate in conventional family life. This ongoing struggle can generate a variety of anxiety, depressive, compulsive, substance abusing, and suicidal states.

Sexual addiction, sexual compulsivity, or the loss of control of sexual behavior is quite common clinically. Clinical contacts with this as a chief complaint have soared in the last decade in response to access to Internet pornography. Treatment for these patterns ranges from 30-day self-pay inpatient 12-stepped modeled programs to self-help groups. Psychiatrists should be cognizant of the relationship between other addictions and unrecognized hypomanic states among these patients.

### The Doctor–Patient Relationship and Sexual Disorders

The main task is to become comfortable listening to sexual stories. Sexual concerns are extremely common in the general population and are more prevalent among those burdened by psychiatric disorders (Dennerstein 2003, Figueira et al. 2001, Kennedy et al. 1999). Although psychiatrists are skillful in assessing individual patients with major psychiatric disorders, we are not nearly as relaxed and confident about our capacities to respond to sexual complaints. Society regards a person's sexuality as an intensely private subject—so private that most people do not have a sufficient vocabulary to describe their own sexual lives. Psychiatrists grow up with these characteristics as well. Most psychiatrists experience a conscious countertransference barrier to exploring sexual issues in detail. This barrier consists of

1. the fear of personal or patient sexual arousal while talking about sex,
2. the fear of not knowing what relevant questions to ask,
3. the fear of not knowing how to help with these problems,
4. the fear of the sudden appearance of awareness of one's own sexual concerns,
5. the fear of having one's moral repugnance show to the patient (Risen 2003).

Excellent training in biological psychiatry has come at the expense of psychotherapy training. This has created the illusion that professional comfort with sexual life is no longer a clinical requirement. Most psychiatrists have no experience with a mentor who has demonstrated that the ordinary fears about dealing with sexual topics can be readily mastered and many patients can be helped through calm perspective-giving psychotherapy.

### FINAL THOUGHTS

A specific diagnosis like vaginismus or GIDNOS does not, per se, dictate the type and course of therapy. The clinician is called upon to weigh many factors in planning treatment. Accurate diagnosis is a vital first step but it quickly gives way to other, more artful considerations. “What factors set up this problem and what forces maintain it? What is the essence of this situation? What does this diagnosis mean in ordinary human terms? Can medication play a useful role? How am I to help? What am I to say? When and how should I say it?” These are essentially psychotherapy considerations. The sexual disorders challenge the doctor to integrate the advances of modern psychiatry with the traditions of less biologically oriented psychiatry and the knowledge accumulating in forensic settings for the purpose of seeing if the patient's distress can be lastingly altered. In this challenge, clinical science inevitably gives way to clinical art. The art involves enabling the patient’s distress to make sense so that the underlying struggle—the developmental task—can be successfully negotiated.

### Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria

For hypoactive sexual desire disorder, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are essentially identical except that ICD-10 specifies a minimum duration of at least 6 months (DSM-IV-TR has no minimum duration).

The ICD-10 Diagnostic Criteria for Research for Sexual Aversion Disorder differs from the DSM-IV-TR criteria in...
several ways. In contrast to DSM-IV-TR, which restricts the condition to the aversion to, and avoidance of, sexual genital contact, ICD-10 also includes presentations characterized by sexual activity resulting in “strong negative feelings and an inability to experience any pleasure.” Furthermore, ICD-10 excludes cases in which the aversion is due to performance anxiety. Finally, ICD-10 specifies a minimum duration of at least 6 months whereas DSM-IV-TR does not specify any minimum duration.

For female sexual arousal disorder and male erectile disorder, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are essentially equivalent except that ICD-10 specifies a minimum duration of at least 6 months. In contrast to DSM-IV-TR, which has male and female versions defined separately, ICD-10 has a single category that applies to both genders.

For premature ejaculation, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are essentially equivalent except that ICD-10 specifies a minimum duration of at least 6 months. Similarly, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria for dyspareunia and vaginismus are essentially equivalent except that ICD-10 specifies a minimum duration of at least 6 months. Furthermore, these conditions are referred to in ICD-10 as “Nonorganic Dyspareunia” and “Nonorganic Vaginismus.”

The definition of a paraphilia is essentially the same in DSM-IV-TR and ICD-10. However, ICD-10 does not include a separate category for Frotteurism and has a combined “Sadomasochism” category.

For GID, ICD-10 defines three separate disorders: “Gender Identity Disorder of Childhood,” “Dual-role Transvestism,” and “Transsexualism” all of which are included under the single DSM-IV-TR category Gender Identity Disorder.

References

Introduction
In the current psychiatric nomenclature of the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR), the eating disorders consist of two clearly defined syndromes: anorexia nervosa and bulimia nervosa. Many individuals presenting for treatment of an eating disorder (Figure 78–1) fail to meet formal criteria for either anorexia nervosa or bulimia nervosa, which raises an important theoretical and practical question: What is an eating disorder? Although this topic has received surprisingly little attention, it has been suggested that a working definition of an eating disorder might be “a persistent disturbance of eating behavior or behavior intended to control weight, which significantly impairs physical health or psychosocial functioning” (Fairburn and Walsh 2002). This definition clearly encompasses the recognized disorders, anorexia nervosa and bulimia nervosa. In addition, it provides a basis for viewing eating disorders as clinically significant problems that may not meet criteria for anorexia nervosa or bulimia nervosa. The term atypical eating disorder is often applied to such problems, even though the number of individuals suffering from them may well outnumber those with “typical” eating disorders. One example of an atypical eating disorder is that of women who are overly concerned about their weight, have dieted to a below-normal weight, but have not ceased menstruating and, therefore, do not meet full criteria for anorexia nervosa. Another is that of individuals who binge and vomit regularly, but at less than the twice-a-week frequency required for bulimia nervosa.

An additional example of a clinically important atypical eating disorder is the occurrence of frequent binge-eating that is not followed by the self-induced vomiting or other inappropriate attempts to compensate, which are characteristic of bulimia nervosa. This disturbance, for which the name binge-eating disorder has been proposed (DSM-IV-TR appendix B) (Yanovski 1993), is a common behavioral pattern among obese individuals who present for treatment at weight loss clinics.

At present, obesity is not considered an eating disorder. Obesity refers to an excess of body fat and is viewed as a general medical, not a psychiatric, condition. Although there is increasing interest in the role of the brain in the development and persistence of obesity, at this stage of our knowledge, obesity is conceived as an etiologically heterogeneous condition, influenced by cultural, environmental, and innate biological factors. It seems appropriate to describe as having an eating disorder only those obese individuals who manifest a clear behavioral abnormality that impairs health or psychosocial functioning have an eating disorder (Devlin, in press).

ANOREXIA NERVOSA

Diagnosis

Definition and Diagnostic Features

History
The syndrome of anorexia nervosa was clearly recognized and, in fact, named in the late nineteenth century. Almost simultaneously, Sir William Gull in England and Charles Lasègue in France described series of cases of young women with impressive weight loss and psychological disturbance. Gull termed this illness “anorexia nervosa” and Lasègue—anorexie hystérique. The salient clinical features described more than 100 years ago are remarkably similar to those presented by patients in the opening years of the twenty-first century.
It is likely that cases of anorexia nervosa were also recognized well before the nineteenth century. In 1689, in a Treatise on Consumptions, Richard Morton (1689) described an 18-year-old girl with amenorrhea and self-imposed weight loss that he attributed to “a multitude of cares and passions of her mind”; this young woman eventually died of her illness, which Morton termed “nervous consumption” to emphasize its important psychological determinants. Bell (1985) has suggested that the fasting and asceticism of some medieval saints might today be viewed as manifestations of an eating disorder (Figure 78–2).

Anorexia nervosa’s long history suggests that although changing cultural norms for what is viewed as esthetically desirable may have played a role in increasing the frequency of anorexia nervosa, they do not fully explain the occurrence of the syndrome.

Definition
The DSM-IV-TR criteria require the individual to be significantly underweight for age and height. Although it is not possible to set a single weight loss standard that applies equally to all individuals, DSM-IV-TR provides a benchmark of 85% of the weight considered normal for age and height as a guideline. Despite being of an abnormally low body weight, individuals with anorexia nervosa are intensely afraid of gaining weight and becoming fat, and remarkably, this fear typically intensifies as the weight falls.

DSM-IV-TR criterion C requires a disturbance in the person’s judgment about his or her weight or shape. For example, despite being underweight, individuals with anorexia nervosa often view themselves or a part of their body as being too heavy. Typically, they deny the grave medical risks engendered by their semistarvation and place
enormous psychological importance on whether they have gained or lost weight. For example, someone with anorexia nervosa may feel intensely distressed if her or his weight increases by half a pound. Finally, criterion D requires that women with anorexia nervosa be amenorrheic.

The DSM-IV-TR criteria for anorexia nervosa are generally consistent with recent definitions and descriptions of this illness. In addition, in DSM-IV-TR, a new subtyping scheme was introduced. DSM-IV-TR suggests that individuals with anorexia nervosa be classed as having one of two variants, either the binge-eating/purging type or the restricting type. Individuals with the restricting type of anorexia nervosa do not engage regularly in either binge-eating or purging and, compared with individuals with the binge-eating/purging form of the disorder, are not as likely to abuse alcohol and other drugs, exhibit less mood lability, and are less active sexually.

Assessment
In assessing individuals who may have anorexia nervosa, it is important to obtain a weight history, including the individual’s highest and lowest weights and the weight he or she would like to have now. For women, it is useful to know the weight at which menstruation last occurred, because it provides an indication of what weight is normal for that individual. The patient should be asked to describe a typical day’s food intake and any food restrictions and dietary practices such as vegetarianism. The psychiatrist should ask whether the patient ever loses control over eating and engages in binge-eating and, if so, the amounts and types of food eaten during such episodes. The use of self-induced vomiting, laxatives, diuretics, enemas, diet pills, and syrup of ipecac to induce vomiting should also be queried.

Physiological Disturbances
An impressive array of physical disturbances has been documented in anorexia nervosa, and the physiological bases of many are understood (Walsh 2005) (Table 78–1). Most of these physical disturbances appear to be secondary consequences of starvation, and it is not clear whether or how the physiological disturbances described here contribute to the development and maintenance of the psychological and behavioral abnormalities characteristic of anorexia nervosa.
This section briefly describes the major physical abnormalities of anorexia nervosa and what is understood about their etiology.

The central nervous system is clearly affected. Computed tomography has demonstrated that individuals with anorexia nervosa have enlarged ventricles, an abnormality that improves with weight gain. It appears that disturbances in serotonergic pathways are present both in the underweight state and following recovery, suggesting that serotonergic abnormalities may play a role in predisposing individuals to the development of anorexia nervosa (Kaye et al. 2005).

Some of the most striking physiological alterations in anorexia nervosa are those of the hypothalamic–pituitary–gonadal axis. In women, estrogen secretion from the ovaries is markedly reduced, accounting for the occurrence of amenorrhea. In analogous fashion, testosterone production is diminished in men with anorexia nervosa. The decrease in gonadal steroid production is due to a reduction in the pituitary's secretion of the gonadotropins luteinizing hormone and follicle-stimulating hormone, which in turn is secondary to diminished release of gonadotropin-releasing hormone from the hypothalamus. Therefore, the amenorrhea of anorexia nervosa is properly viewed as a type of hypothalamic amenorrhea. These changes appear mediated to a substantial degree by marked reductions in the serum level of leptin, reflecting undernutrition and decreased body fat mass.

In an adult with anorexia nervosa, the status of the hypothalamic–pituitary–gonadal axis resembles that of a pubertal or prepubertal child—the secretion of estrogen or testosterone, of luteinizing hormone and follicle-stimulating hormone and of gonadotropin-releasing hormone, is reduced. This endocrinological picture may be contrasted with that of postmenopausal women who have a similar reduction in estrogen secretion but who, unlike women with anorexia nervosa, show increased pituitary gonadotropin secretion. Furthermore, even the circadian patterns of luteinizing hormone and follicle-stimulating hormone secretion in adult women with anorexia nervosa closely resemble the patterns normally seen in pubertal and prepubertal girls (Figure 78–3). Although similar abnormalities are also seen in other forms of hypothalamic amenorrhea and are therefore not specific to anorexia nervosa, it is nonetheless striking that this syndrome is accompanied by a physiological arrest or regression of the reproductive endocrine system.

The functioning of other hormonal systems is also disrupted in anorexia nervosa, although typically not as profoundly as is the reproductive axis. Presumably as part of the metabolic response to semistarvation, the activity of the thyroid gland is reduced. Plasma thyroxine levels are somewhat diminished, but the plasma level of the pituitary hormone and thyroid-stimulating hormone is not elevated. The activity of the hypothalamic–pituitary–adrenal axis is increased, as indicated by elevated plasma levels of cortisol and resistance to dexamethasone suppression. The regulation of vasopressin (antidiuretic hormone) secretion from the posterior pituitary is disturbed, contributing to the development of partial diabetes insipidus in some individuals.
Anorexia nervosa is often associated with the development of hypokalemia and of a normochromic, normocytic anemia of mild-to-moderate severity. Surprisingly, leukopenia does not appear to result in a high vulnerability to infectious illnesses. Serum levels of liver enzymes are sometimes elevated, particularly during the early phases of refeeding, but the synthetic function of the liver is rarely seriously impaired so that the serum albumin concentration and the prothrombin time are usually within normal limits. Serum cholesterol levels are sometimes elevated in anorexia nervosa, although the basis of this abnormality remains obscure. In some patients, self-imposed fluid restriction and excessive exercise produce dehydration and elevations of serum creatinine and blood urea nitrogen. In others, water loading may lead to hyponatremia. The status of serum electrolytes is a reflection of the individual’s salt and water intake and the nature and severity of the purging behavior. A common pattern is hypokalemia, hypochloremia, and mild alkalosis resulting from frequent and persistent self-induced vomiting.

It has become clear that individuals with anorexia nervosa have decreased bone density compared with age- and sex-matched peers and, as a result, are at increased risk of fractures. Low levels of estrogen, high levels of cortisol, and poor nutrition have been cited as risk factors for the development of reduced bone density in anorexia nervosa. Theoretically, estrogen treatment might reduce the risk of osteoporosis in women who are chronically amenorrheic, with a deficit in polymorphonuclear leukocytes leading to a relative lymphocytosis. Elevations of blood urea nitrogen and serum creatinine concentrations may occur because of dehydration, which can also artificially elevate the hemoglobin and hematocrit. A variety of electrolyte abnormalities may be observed, reflecting the state of hydration and the history of vomiting and diuretic and laxative abuse. Serum levels of liver enzymes are usually normal but may transiently increase during refeeding. Cholesterol levels may be elevated.

Abnormalities of cardiac function include bradycardia and hypotension, which are occasionally symptomatic. The pump function of the heart is compromised, and congestive heart failure occasionally develops in individuals during overly rapid refeeding. The electrocardiogram shows sinus bradycardia and a number of nonspecific abnormalities. Arrhythmias may develop, often in association with fluid and electrolyte disturbances. It has been suggested that significant prolongation of the QT interval may be a harbinger of life-threatening arrhythmias in some individuals with anorexia nervosa, but this has not been conclusively demonstrated.

The motility of the gastrointestinal tract is diminished, leading to delayed gastric emptying and contributing to complaints of bloating and constipation. Rare cases of acute gastric dilatation or gastric rupture, which is often fatal, have been reported in individuals with anorexia nervosa who consumed large amounts of food when binge-eating.

As already noted, virtually all of the physiological abnormalities described in individuals with anorexia nervosa are also seen in other forms of starvation, and most improve or disappear as weight returns to normal. Therefore, weight restoration is essential for physiological recovery. More surprisingly, perhaps, weight restoration is believed to be essential for psychological recovery as well. Accounts of human starvation amply document the profound impact of starvation on mental health. Starving individuals lose their sense of humor and interest in friends and family fades, and mood generally becomes depressed. They may develop peculiar behavior similar to that of patients with anorexia nervosa, such as hoarding food or concocting bizarre food combinations. If starvation disrupts psychological and behavioral functioning in normal individuals, it presumably does so as well in those with anorexia nervosa. Thus, correction of starvation is a prerequisite for the restoration of both physical and psychological health.

Physical Examination and Laboratory Findings
The patient should be weighed, or a current weight should be obtained from the patient’s general physician. Blood pressure, pulse, and body temperature are often below the lower limit of normal. On physical examination, lanugo, a fine, downy hair normally seen in infants, may be present on the back or the face. The extremities are frequently cold and have a slight red-purple color (acrocyanosis). Edema is rarely observed at the initial presentation but may develop transiently during the initial stages of refeeding.

The basis for laboratory abnormalities is presented in the earlier section on physiological disturbances. Common findings are a mild-to-moderate normochromic, normocytic anemia and leukopenia, with a deficit in polymorphonuclear leukocytes leading to a relative lymphocytosis. Elevations of blood urea nitrogen and serum creatinine concentrations may occur because of dehydration, which can also artificially elevate the hemoglobin and hematocrit. A variety of electrolyte abnormalities may be observed, reflecting the state of hydration and the history of vomiting and diuretic and laxative abuse. Serum levels of liver enzymes are usually normal but may transiently increase during refeeding. Cholesterol levels may be elevated.

The electrocardiogram typically shows sinus bradycardia and, occasionally, low QRS voltage and a prolonged QT interval; a variety of arrhythmias have also been described.

Epidemiology
Anorexia nervosa is a relatively rare illness. Even among high-risk groups, such as adolescent girls and young women, the point prevalence of strictly defined anorexia nervosa is only about 0.5%. The prevalence rates of partial syndromes are substantially higher (Van Hoeken et al. 1998). Some, but not all, studies suggest that its incidence has increased significantly during the last 50 years, a phenomenon usually attributed to changes in cultural norms regarding desirable body shape and weight.

Anorexia nervosa usually affects women; the ratio of men to women is approximately 1:10 to 1:20. Anorexia nervosa occurs primarily in industrialized and affluent countries, and some data suggest that, even within those countries, anorexia nervosa is more common among the higher socioeconomic classes. Some occupations, such as ballet dancing and fashion modeling, appear to confer a particular high risk for the development of anorexia nervosa. Thus, anorexia nervosa appears more likely to develop in an environment in which food is readily available but in which, for women, being thin is somehow equated with higher or special achievement.

Comorbidity Patterns
Symptoms of mood and anxiety disturbances, especially obsessive–compulsive disorder, are commonly observed among individuals with anorexia nervosa. These symptoms improve substantially with weight gain but often do not resolve completely. Some individuals, especially those with the binge/purge subtype, may also have problems with substance abuse.
Course

Onset

Anorexia nervosa often begins innocently. Typically, an adolescent girl or young woman who is of normal weight or, perhaps, a few pounds overweight decides to diet. This decision may be prompted by an important but not extraordinary life event, such as leaving home for camp, attending a new school, or a casual unflattering remark by a friend or family member. Initially, the dieting seems no different from that pursued by many young women, but as weight falls, the dieting intensifies. The restrictions become broader and more rigid; for example, desserts may first be eliminated, then meat, and then any food that is thought to contain fat. The person becomes increasingly uncomfortable if she is seen eating and avoids meals with others. Food seems to assume a moral quality so that vegetables are viewed as “good” and anything with fat is “bad.” The individual has idiosyncratic rules about how much exercise she must do, and when, where, and how she can eat.

Food avoidance and weight loss are accompanied by a deep and reassuring sense of accomplishment, and weight gain is viewed as a failure and a sign of weakness. Physical activity, such as running or aerobic exercise, often increases as the dieting and weight loss develop. Inactivity and complaints of weakness usually occur only when emaciation has become extreme. The person becomes more serious and devotes little effort to anything but work, dieting, and exercise. She may become depressed and emotionally labile, socially withdrawn, and secretive, and she may lie about her eating and her weight. Despite the profound disturbances in her view of her weight and calorie needs, reality testing in other spheres is intact, and the person may continue to function well in school or at work. Symptoms usually persist for months or years until, typically at the insistence of friends or family, the person reluctantly agrees to see a professional.

Natural History

The course of anorexia nervosa is enormously variable. Some individuals have mild and brief illnesses and either never come to medical attention or are seen only briefly by their pediatrician or general medical physician. It is difficult to estimate the frequency of this phenomenon because such individuals are rarely studied.

Most of the literature on course and outcome is based on individuals who have been hospitalized for anorexia nervosa. Although such individuals presumably have a relatively severe illness and adverse outcomes, a substantial fraction, probably between one-third and one-half, makes full and complete psychological and physical recoveries. On the other hand, anorexia nervosa is also associated with an impressive long-term mortality. The best data currently available suggest that 10–20% of patients who have been hospitalized for anorexia nervosa will, in the next 10–30 years, die as a result of their illness. Much of the mortality is due to severe and chronic starvation, which eventually terminates in sudden death. In addition, a significant fraction of patients commit suicide.

Between these two extremes are a large number of individuals whose lives are impaired by persistent difficulties with eating. Some are severely affected, maintaining a chronic state of semistarvation, bizarre eating rituals, and social isolation; others may gain weight but struggle with bulimia nervosa and strict rules about food and eating; and still others may recover initially but then relapse into another full episode. There is a high frequency of depression among individuals who have had anorexia nervosa and a significant frequency of drug and alcohol abuse, but psychotic disorders develop only rarely. Thus, in general, individuals either recover or continue to struggle with psychological and behavioral problems that are directly related to the eating disorder. It is of note that it is rare for individuals who have had anorexia nervosa to become obese.

It is difficult to specify factors that account for the variability of outcome in anorexia nervosa. A significant body of experience suggests that adolescents with a short duration of illness have the best prognosis, but there are also suggestions that prepubertal onset may portend a difficult course. It is likely that the severity of the illness (e.g., the lowest weight reached and the number of hospitalizations) and the presence of associated symptoms, such as binge-eating and purging, also contribute to poor outcome. However, it is impossible to predict course and outcome in an individual with any certainty.

Differential Diagnosis

In general, anorexia nervosa is not difficult to recognize. Uncertainty surrounding the diagnosis sometimes occurs in young adolescents who may not clearly describe a drive for thinness and the fear of becoming fat. Rather, they may acknowledge only a vague concern about consuming certain foods and an intense desire to exercise. It can also be difficult to elicit the distorted view of shape and weight (criterion C) from patients who have had anorexia nervosa for many years. Such individuals may state that they realize they are too thin and may make superficial efforts to gain weight, but they do not seem particularly concerned about the physical risks or deeply committed to increasing their calorie consumption.

Although depression, schizophrenia, and obsessive–compulsive disorder may be associated with disturbed eating and weight loss, it is rarely difficult to differentiate these disorders from anorexia nervosa. Individuals with major depression may lose significant amounts of weight but do not exhibit the relentless drive for thinness characteristic of anorexia nervosa. In schizophrenia, starvation may occur because of delusions about food, for example, that it is poisoned. Individuals with obsessive–compulsive disorder may describe irrational concerns about food and develop rituals related to meal preparation and eating but do not describe the intense fear of gaining weight and the pervasive wish to be thin that characterize anorexia nervosa.

A wide variety of medical problems cause serious weight loss in young people and may at times be confused with anorexia nervosa. Examples of such problems include gastric outlet obstruction, Crohn’s disease, and brain tumors. Individuals whose weight loss is due to a general medical illness generally do not show the drive for thinness, the fear of gaining weight, and the increased physical activity characteristic of anorexia nervosa. However, the psychiatrist is well advised to consider any chronic medical illness associated with weight loss, especially when evaluating individuals with unusual clinical presentations such as late age at onset or prominent physical complaints, for example, pain and gastrointestinal cramping while eating.
Differences in Presentation
The symptoms of anorexia nervosa are remarkably homogeneous, and differences between patients in clinical manifestations are fewer than in most psychiatric illnesses. Younger patients may not express verbally the characteristic fear of fatness or the overconcern with shape and weight, and some patients with long-standing anorexia nervosa may express a desire to gain weight but be unable to make persistent changes in their behavior. It has been suggested that in other cultures, the rationale given by patients for losing weight differs from the fear of fatness characteristic of cases in North America. For example, the features of weight phobia, fear of fatness, and pursuit of thinness have been described as being absent in some patients in Hong Kong and India who, in other regards, present symptoms that closely resemble those of anorexia nervosa; reasons for food refusal given by such patients include lack of appetite and epigastric bloating (Keel and Klump 2003).

Men have anorexia nervosa far less frequently than women. However, when the syndrome does develop in a man, it is typical.

Etiology and Pathophysiology

Introduction
At present, the etiology of anorexia nervosa is fundamentally unknown. However, from several sources, it is possible to identify risk factors whose presence increases the likelihood of anorexia nervosa. It is also possible to describe the course and complications of the syndrome and to suggest interactions between features of the disorder, for example, between malnutrition and psychiatric illness. Thus, as indicated in Figure 78–4, the difficulties that lead to the development of anorexia nervosa may be distinct from the forces that intensify the symptoms and perpetuate the illness once it has begun.

Genetic Factors
Anorexia nervosa occurs more frequently in biological relatives of patients who present with the disorder. The prevalence rate of anorexia nervosa among sisters of patients is estimated to be approximately 6%; the morbidity risk among other relatives ranges from 2% to 4%. Some evidence for a genetic component in the etiology of anorexia nervosa comes from twin studies, which reported substantially higher concordance rates for monozygotic than for dizygotic twin pairs (Klump et al. 2001). However, conclusive data for genetic transmission of the disorder are not yet available.

Developmental Factors
Because anorexia nervosa typically begins during adolescence, developmental issues are thought to play an important etiological role. Critical challenges at this time of life include the need to establish independence, a well-defined personal identity, fulfilling relationships, and clear values and principles to govern one’s life. Family struggles, conflicts regarding sexuality, and pressures regarding increased heterosexual contact are also common. However, it is not clear that difficulties over these issues are more salient for individuals who will develop anorexia nervosa than for other adolescents. Depression has been implicated as a nonspecific risk factor, and higher levels of depressive symptoms as well as insecurity, anxiety, and self-consciousness have been documented in adolescent girls in comparison with adolescent boys. Similarly, the progression of physical and sexual maturation and the concomitant increase in women’s percentage of body fat may have a substantial impact on the self-image of adolescent girls, particularly because the relationship between self-esteem and satisfaction with physical appearance and body characteristics is stronger in women than in men.

Psychological Factors

Psychological Functioning
Various psychoanalytic theories have been postulated (e.g., defense against fantasies of oral impregnation, underlying deficits in the development of object relations, and deficits in self-structure), but such hypotheses are difficult to verify. Bruch (1973, 1982) suggested that anorexia nervosa stems from failures in early attachment, attempts to cope with underlying feelings of ineffectiveness and inadequacy, and an inability to meet the demands of adolescence and young adulthood. These ideas, as well as her conceptualization that the single-minded focus on losing weight in anorexia nervosa is the concrete manifestation of a struggle to achieve a sense of identity, purpose, specialness, and control, are compelling and clinically useful. Cognitive–behavioral theories emphasize the distortions and dysfunctional thoughts (e.g., dichotomous thinking) that may stem from various causal factors, all of which eventually focus on the belief that it is essential to be thin.

Personality Traits
Although the existence of a specific predisposing personality style has not been conclusively documented, certain traits have commonly been reported among women with anorexia nervosa. Women hospitalized for anorexia nervosa have greater self-discipline, conscientiousness, and emotional caution than women hospitalized for bulimia nervosa and women with no eating disorders (Casper et al. 1992). In addition, even after they have recovered from their illness, women who have had anorexia nervosa tend to avoid risks and to exhibit high levels of caution in emotional expression.
and strong compliance with rules and moral standards (Srinivasagam et al. 1995).

Familial Factors
Individual psychiatric disorders in parents, dysfunctional family relationships, and impaired family interaction patterns have been implicated in the etiology of anorexia nervosa. Mothers of individuals with anorexia nervosa are often described as overprotective, intrusive, perfectionistic, and fearful of separation; fathers are described as withdrawn, passive, emotionally constricted, obsessional, moody, and ineffectual. Family system theorists have suggested that impaired family interactions such as pathological enmeshment, rigidity, overprotectiveness, and difficulties confronting and resolving conflicts are central features of anorexic pathology (Minuchin et al. 1978). However, few empirical studies have been conducted to date, particularly studies that also examine psychiatrically or medically ill comparison groups. Therefore, the precise role of the family in the development and course of anorexia nervosa, although undoubtedly important, has not been clearly delineated.

Social/Environmental Factors
It has been suggested that an increased prevalence of anorexia nervosa is related to the current emphasis in contemporary Western society on an unrealistically thin appearance in women. There is substantial evidence that a desire to be slim is common among middle- and upper-class white women and that this emphasis on slimmness has increased significantly during the past several decades. In the USA, anorexia nervosa develops more frequently in white adolescents than in adolescents from other racial groups. A variety of characteristics may protect African-American girls from developing eating disorders, including more acceptance of being overweight, more satisfaction with their body image, and less social pressure regarding weight (Striegel-Moore et al. 2003).

It has also been suggested that the emphasis of contemporary Western society on achievement and performance in women, which is a shift from the more traditional emphasis on deference, compliance, and unassertiveness, has left many young women vulnerable to the development of eating disorders such as anorexia nervosa. These multiple and contradictory role demands are embodied within the modern concept of a superwoman who performs all of the expected roles (e.g., is competent, ambitious, and achieving, yet also feminine, nurturing, and sexual) and, in addition, devotes considerable attention to her appearance (Gordon 2000). Other authors have noted that the core features of anorexia nervosa have been described in other cultural settings, indicating that the current societal emphasis on thinness is not a necessary precondition for the development of this syndrome (Keel and Klump 2003).

Treatment

Goals of Treatment
The first goal of treatment is to engage the patient and her or his family. For most patients with anorexia nervosa, this is challenging. Patients usually minimize their symptoms and suggest that the concerns of the family and friends, who have often been instrumental in arranging the consultation, are greatly exaggerated. It is helpful to identify a problem that the patient can acknowledge, such as weakness, irritability, difficulty concentrating, or trouble with binge-eating. The psychiatrist may then attempt to educate the patient regarding the pervasive physical and psychological effects of semistarvation and about the need for weight gain if the acknowledged problem is to be successfully addressed.

A second goal of treatment is to assess and address acute medical problems, such as fluid and electrolyte disturbances and cardiac arrhythmias. Depending on the severity of illness, this may require the involvement of a general medical physician.

The additional but most difficult and time-consuming goals are the restoration of normal body weight, the normalization of eating, and the resolution of the associated psychological disturbances. The final goal is the prevention of relapse.

Initiation of Treatment
A common major impediment to the treatment of patients with anorexia nervosa is their disagreement with the goals of treatment; many of the features of their illness are simply not viewed by patients as a problem. In addition, this may be compounded by a variety of concerns of the patient, such as basic mistrust of relationships, feelings of vulnerability and inferiority, and sensitivity to perceived coercion. Such concerns may be expressed through considerable resistance, defiance, or pseudocompliance with the psychiatrist’s interventions and contribute to the power struggles that often characterize the treatment process. The psychiatrist must try to avoid colluding with the patient’s attempts to minimize problems but at the same time allow the patient enough independence to maintain the alliance. Dealing with such dilemmas is challenging and requires an active approach on the part of the psychiatrist. In most instances, it is possible to preserve the alliance while, nonetheless, adhering to established limits and the need for change.

The initial stage of treatment should be aimed at reversing the nutritional and behavioral abnormalities (Figure 78–5). The intensity of the treatment required and the need for partial or full hospitalization should be determined by the current weight, the rapidity of weight loss, and the severity of associated medical and behavioral problems and other symptoms such as depression. In general, patients whose weights are less than 75% of expected should be viewed as medically precarious and require intensive treatment such as hospitalization.

Weight Restoration
Most inpatient or day-treatment units experienced in the care of patients with anorexia nervosa use a structured treatment approach that relies heavily on supervision of calorie intake by the staff. Patients are initially expected to consume sufficient calories to maintain weight, usually requiring 1500–2000 kcal/day in four to six meals. After the initial medical assessment has been completed and weight has stabilized, calorie intake is gradually increased to an amount necessary to gain 2–5 lb/week. Because the consumption of approximately 4000 kcal beyond maintenance requirements is needed for each pound of weight gain, the daily calorie requirements become impressive, often in the range of 4000 kcal/day. Some eating disorder units provide only
Psychosocial Treatments

As weight increases, individual, group, and family psychotherapy can begin to address other issues in addition to the distress engendered by gaining weight (Garner and Garfinkel 1997). For example, it is typically important for patients to recognize that they have come to base much of their self-esteem on dieting and weight control and are likely to judge themselves according to harsh and unforgiving standards. Similarly, patients should be helped to see how the eating disorder has interfered with the achievement of personal goals such as education, sports, or making friends.

There is, at present, no general agreement about the most useful type of psychotherapy or the specific topics that need to be addressed. Most eating disorder programs employ a variety of psychotherapeutic interventions. A number of psychiatrists recommend the use of individual and group psychotherapy using cognitive–behavioral techniques to modify the irrational overemphasis on weight. Although most authorities see little role for traditional psychoanalytic therapy, individual and group psychodynamic therapy can address such problems as insecure attachment, separation and individuation, sexual relationships, and other interpersonal concerns.

Family Treatment

There is good evidence supporting the involvement of the family in the treatment of younger patients with anorexia nervosa. Family therapy can be helpful in addressing family members’ fears about the illness; interventions typically emphasize parental cooperation, mutual support and consistency, and establishing boundaries regarding the patient’s symptoms and other aspects of his or her life.

In recent years, Lock et al. (2000) have described a novel approach that has come to be known as the “Maudsley method.” In this family-based treatment, the parents are charged with the responsibility of refeeding, with the support and guidance of the therapist. This approach, which differs fundamentally from the traditional stance that encouraged parents to withdraw from the day-to-day management of eating, appears quite promising.

Somatic Treatments

Despite the multiple physiological disturbances associated with anorexia nervosa, there is no clearly established role for medication (Zhu and Walsh 2002). The earliest systematic medication trials in anorexia nervosa focused on the use of neuroleptics. Theoretically, such agents might help to promote weight gain, reduce physical activity, and diminish the distorted thinking about shape and weight, which often reaches nearly delusional proportions. Early work in the late 1950s and 1960s using chlorpromazine led to substantial enthusiasm, but two placebo-controlled trials of the neuroleptics, sulpiride and pimozide, were unable to establish significant benefits. In recent years, interest has grown in taking advantage of the impressive weight gain associated with some atypical antipsychotics; however, no controlled data supporting this intervention have yet appeared.

Four controlled studies, three of tricyclic antidepressants and one of fluoxetine, have examined the use of antidepressants in the treatment of underweight patients with anorexia nervosa, and none has suggested substantial benefit from medication. Therefore, despite the frequency of

Figure 78–5 Algorithm for choice of initial treatment of anorexia nervosa.
depressive symptoms among patients with anorexia nervosa, there is no good evidence supporting the use of antidepressant medication in their treatment.

Prevention of Relapse
A large percentage of patients with anorexia nervosa remain chronically ill; 30–50% of patients successfully treated in the hospital require rehospitalization within 1 year of discharge. Therefore, posthospitalization outpatient treatments are recommended to prevent relapse and improve overall short- and long-term functioning. Cognitive–behavioral treatment appears to reduce the rate of relapse, but a recent study found that the addition of fluoxetine did not augment the utility of this psychological intervention (Walsh et al. 2006).

Treatment-Refractory Patients
Some patients with anorexia nervosa refuse to accept treatment and thereby can raise difficult ethical issues. If weight is extremely low or there are acute medical problems, it may be appropriate to consider involuntary commitment. For patients who are ill but more stable, the psychiatrist must weigh the short-term utility of involuntary treatment against the disruption of a potential alliance with the patient.

The goals of treatment may need to be modified for patients with chronic illness who have failed multiple previous attempts at inpatient and outpatient care. Treatment may be appropriately aimed at preventing further medical, psychological, and social deterioration in the hope that the anorexia nervosa may eventually improve with time.

BULIMIA NERVOSA

Definition and Diagnostic Features

History
Overeating has presumably been a problem for humans for millennia. However, interest in a disorder related to anorexia nervosa but characterized behaviorally by persistent binge-eating grew dramatically in the late 1970s and early 1980s, driven by the appearance of increasing numbers of patients with the chief complaint of binge-eating. In an article published in 1979, Russell (1979) clearly delineated patients with the chief complaint of binge-eating. In an 1980s, driven by the appearance of increasing numbers of binge-eating grew dramatically in the late 1970s and early

DSM-IV-TR Criteria

Bulimia Nervosa

A. Recurrent episodes of binge-eating. An episode of binge-eating is characterized by both of the following:

1. eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
2. a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.

C. The binge-eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.

D. Self-evaluation is unduly influenced by body shape and weight.

E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify type:

Purging type: during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

Nonpurging type: during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

not be a sharp one, both patients’ reports and laboratory studies of eating behavior clearly indicate that, when binge-eating, patients with bulimia nervosa do indeed consume larger than normal amounts of food (Walsh et al. 1992).

Episodes of binge-eating are associated, by definition, with a sense of loss of control. Once the eating has begun, the individual feels unable to stop until an excessive amount has been consumed. This loss of control is eating).
to avoid weight gain. Most patients who present to eating disorders clinics with this syndrome report self-induced vomiting or the abuse of laxatives. Other methods include misusing diuretics, fasting for long periods, and exercising extensively after eating binges.

The DSM-IV-TR criteria require that the overeating episodes and the compensatory behaviors both occur at least twice a week for 3 months to merit a diagnosis of bulimia nervosa. This criterion, although useful in preventing the diagnostic label from being applied to individuals who only rarely have difficulty with binge-eating, is clearly an arbitrary one.

Criterion D in the DSM-IV-TR definition of bulimia nervosa requires that individuals with bulimia nervosa exhibit an overconcern with body shape and weight. That is, they tend to base much of their self-esteem on how much they weigh and how slim they look.

Finally, in the DSM-IV-TR nomenclature, the diagnosis of bulimia nervosa is not given to individuals with anorexia nervosa. Individuals with anorexia nervosa who recurrently engage in binge-eating or purging behavior should be given the diagnosis of anorexia nervosa, binge-eating/purging subtype, rather than an additional diagnosis of bulimia nervosa. This is a change from the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) system, in which both diagnoses could be given simultaneously.

In DSM-IV-TR, a subtyping scheme was introduced for bulimia nervosa in which patients are classed as having either the purging or the nonpurging type of bulimia nervosa. This scheme was introduced for several reasons. First, those individuals who purge are at greater risk of developing fluid and electrolyte disturbances such as hypokalemia. Second, data suggest that individuals with the nonpurging type of bulimia nervosa weigh more and have less psychiatric illness compared with those with the purging type. Finally, most of the published literature on the treatment of bulimia nervosa has been based on studies of individuals with the purging type of this disorder.

Assessment
The assessment of individuals who may have bulimia nervosa is similar to that described for anorexia nervosa. The patient should be asked to describe a typical day’s food intake and a typical binge, and the interviewer should assess whether the patient does indeed consume an unusually large amount of food, as required by the DSM-IV-TR definition of a binge. The interviewer should explicitly inquire about self-induced vomiting. The interviewer should ask about the use of laxatives, diuretics, diet pills, and enemas. A weight history should be obtained, so the interviewer can determine whether the binge-eating was preceded by anorexia nervosa, as is often the case, or by obesity. Because there is substantial comorbidity, the interviewer should ascertain whether there is a history of anxiety or mood disturbance or of substance abuse.

Physiological Disturbances
In a small fraction of individuals, bulimia nervosa is associated with the development of fluid and electrolyte abnormalities that result from the self-induced vomiting or the misuse of laxatives or diuretics. The most common electrolyte disturbances are hypokalemia, hyponatremia, and hypochloremia. Patients who lose substantial amounts of stomach acid through vomiting may become slightly alkalotic; those who abuse laxatives may become slightly acidic.

There is an increased frequency of menstrual disturbances such as oligomenorrhea among women with bulimia nervosa. Several studies suggest that the hypothalamic–pituitary–gonadal axis is subject to the same type of disruption as in anorexia nervosa but that the abnormalities are much less frequent and severe.

Patients who induce vomiting for many years may develop dental erosion, especially of the upper front teeth (Figure 78-6). The mechanism appears to be that stomach acid softens the enamel, which in time gradually disappears so that the teeth chip more easily and can become reduced in size. Some patients develop painless salivary gland enlargement, which is thought to represent hypertrophy resulting from the repeated episodes of binge-eating and vomiting. The serum level of amylase is sometimes mildly elevated in patients with bulimia nervosa because of increased amounts of salivary amylase.

Most patients with bulimia nervosa have surprisingly few gastrointestinal abnormalities. As indicated earlier, it appears that the disorder is associated with an enlarged gastric capacity and delayed gastric emptying, but these abnormalities are not so severe as to be detectable on routine clinical examination. Potentially life-threatening complications such as an esophageal tear or gastric rupture occur, but fortunately rarely.

The long-standing use of syrup of ipecac to induce vomiting can lead to absorption of some of the alkaloids and permanent damage to nerve and muscle, including clinically significant cardiomyopathy.

Physical Examination and Laboratory Findings
The patient should be weighed and the presence of dental erosion noted. Routine laboratory testing reveals an abnormality of fluid and electrolyte balance such as those described in the section on physiological disturbances in 5–10% of patients with bulimia nervosa.

Epidemiology
Soon after bulimia nervosa was recognized as a distinct disorder, surveys indicated that many young women reported problems with binge-eating, and it was suggested that the syndrome of bulimia nervosa was occurring in epidemic proportions. Later careful studies have found that
although binge-eating is frequent, the full-blown disorder of bulimia nervosa is much less common, with a lifetime prevalence of 1–2% among women in the USA (Hudson et al. 2007). Although the epidemiological data are limited, they suggest a significant increase in the incidence of bulimia nervosa in the last several decades (Keel and Klump 2003).

Comorbidity Patterns
Among patients with bulimia nervosa who are seen at eating disorders clinics, there is an increased frequency of anxiety and mood disorders, especially major depressive disorder and dysthymic disorder; drug and alcohol abuse; and personality disorders. It is not certain whether this comorbidity is also observed in community samples or whether it is a characteristic of individuals who seek treatment.

Course
Onset
Bulimia nervosa typically begins after a young woman who sees herself as somewhat overweight starts a diet and, after some initial success, begins to overeat. Distressed by her lack of control and fear of gaining weight, she decides to compensate for the overeating by inducing vomiting or taking laxatives, methods she has heard about from friends or seen in media reports about eating disorders. After discovering that she can successfully purge, the individual may, for a time, feel pleased in that she can eat large amounts of food and not gain weight. However, the episodes of binge-eating usually increase in size and in frequency and occur after a variety of stimuli, such as transient depression or anxiety or a sense that she has begun to overeat. Patients often describe themselves as “numb” while they are binge-eating, suggesting that the eating may serve to avoid uncomfortable emotional states. Patients usually feel intensely ashamed of their “disgusting” habit and may become depressed by their lack of control over their eating.

Once established, the binge-eating tends to occur in the late afternoon or evening and almost always while the patient is alone. The typical patient presenting to eating disorders clinics has been binge-eating and inducing vomiting five to 10 times weekly for 3–10 years. Although there is substantial variation, binges tend to contain 1000 or more calories and to consist of sweet, high-fat foods that are normally consumed as dessert, such as ice cream, cookies, and cake. Although patients complain of “carbohydrate craving,” they only rarely binge-eat foods that are pure carbohydrates, such as fruits. Patients usually induce vomiting or use their characteristic compensatory behavior immediately after the binge and feel substantial relief that the calories are “gone.” In reality, it appears that vomiting is the only purging method capable of disposing of a significant number of ingested calories. The weight loss associated with the misuse of laxatives and diuretics is primarily due to the loss of fluid and electrolytes, not calories.

When not binge-eating, patients with bulimia nervosa tend to restrict their calorie intake and to avoid the foods usually consumed during episodes of binge-eating. Although there is phenomenological resemblance between binge-eating and substance abuse, there is no evidence that physiological addiction plays a role in bulimia nervosa. On the other hand, similar brain mechanisms mediate the reward both of eating and of abuse drugs, suggesting that a “final common pathway” may underlie the similarities in symptoms.

Natural History
Over time, the symptoms of bulimia nervosa tend to improve, although a substantial fraction of individuals continue to engage in binge-eating and purging (Keel et al. 1999). Treatment intervention appears to reduce the length of illness. It is not clear what other factors are most predictive of good outcome, but those individuals who cease binge-eating and purging completely during treatment are least likely to relapse (Olmstead et al. 1994).

Differential Diagnosis
Bulimia nervosa is not difficult to recognize if a full history is available. The binge-eating/purging type of anorexia nervosa has much in common with bulimia nervosa but is distinguished by the characteristic low body weight and, in women, amenorrhea. Some individuals with atypical forms of depression overeat when depressed; if the overeating meets the definition of a binge described previously (i.e., a large amount of food is consumed with a sense of loss of control), and if the binge-eating is followed by inappropriate compensatory behavior, occurs sufficiently frequently, and is associated with overconcern regarding body shape and weight, an additional diagnosis of bulimia nervosa may be warranted. Some individuals become nauseated and vomit when upset; this and similar problems are probably not closely related to bulimia nervosa and should be viewed as a somatoform disorder.

Many individuals who believe they have bulimia nervosa have a symptom pattern that fails to meet full diagnostic criteria because the frequency of their binge-eating is less than twice a week or because what they view as a binge does not contain an abnormally large amount of food. Individuals with these characteristics fall into the broad and heterogeneous category of atypical eating disorders. Binge-eating disorder (see section on binge-eating disorder), a category currently included in the DSM-IV-TR Appendix B for categories that need additional research, is characterized by recurrent binge-eating similar to that seen in bulimia nervosa but without the regular occurrence of inappropriate compensatory behavior.

Differences in Presentation
Probably the greatest difference in presentation is between those individuals who purge and those who do not. Individuals with the nonpurging form of bulimia nervosa are more likely to be overweight at the time of presentation and to exhibit less general psychiatric illness compared with individuals who induce vomiting.

Etiology and Pathophysiology
As in the case of anorexia nervosa, the etiology of bulimia nervosa is uncertain. Several factors clearly predispose individuals to the development of bulimia nervosa, including being an adolescent girl or young adult woman. A personal or family history of obesity and of mood disturbance also appears to increase risk. Twin studies have suggested that inherited factors are related to the risk of developing bulimia nervosa, but what these factors are and how they operate are unclear.
Many of the same psychosocial factors related to the development of anorexia nervosa are also applicable to bulimia nervosa, including the influence of cultural esthetic ideals of thinness and physical fitness. Similarly, bulimia nervosa primarily affects women; the ratio of men to women is approximately 1:10. It also occurs more frequently in certain occupations (e.g., modeling and sports (e.g., wrestling, running).

Psychological Factors
Although not proven, it seems likely that several factors serve to perpetuate the binge-eating once it has begun (Figure 78–7). First, most individuals with bulimia nervosa, because of both their concern regarding weight and their worry about the effect of the binge-eating, attempt to restrict their food intake when they are not binging. The psychological and physiological restraint that is thereby entailed presumably makes additional binge-eating more likely. Second, even if mood disturbance is not present at the outset, individuals become distressed about their inability to control their eating, and the resultant lowering of self-esteem contributes to disturbances of mood and to a reduced ability to control impulses to overeat. In addition, cognitive-behavioral theories emphasize the role of rigid rules regarding food and eating, and the distorted and dysfunctional thoughts that are similar to those seen in anorexia nervosa. Interpersonal theories also implicate interpersonal stressors as a primary factor in triggering binge-eating. There is no evidence to suggest that a particular personality structure is characteristic of women with bulimia nervosa (Wonderlich 2002).

It has been suggested that childhood sexual abuse is a specific risk factor for the development of bulimia nervosa. Scientific support for this hypothesis is weak. The best studies to date have found that compared with women without psychiatric illness, women with bulimia nervosa do indeed report increased frequencies of sexual abuse. However, the rates of abuse are similar to those found in other psychiatric disorders and occur in a minority of women with bulimia nervosa. Thus, while early abuse may predispose an individual to psychiatric problems generally, it does not appear to lead specifically to an eating disorder, and most patients with bulimia nervosa do not have histories of sexual abuse (Welch and Fairburn 1994).

Neurobiological Factors
There are also indications that bulimia nervosa is accompanied by physiological disturbances that disrupt the development of satiety during a meal and therefore increase the likelihood of binge-eating. These disturbances include an enlarged stomach capacity, a delay in stomach emptying, and a reduction in the release of cholecystokinin, a peptide hormone secreted by the small intestine during a meal that normally plays a role in terminating eating behavior (Klein and Walsh 2004). All these abnormalities appear to predispose the individual to overeat and therefore to perpetuate the cycle of binge-eating.

Social/Environmental Factors
Evidence suggests an important role of sociocultural influences in the development of bulimia nervosa. For example, the frequency of the disorder appears to be very low in non-Western societies, and to have increased substantially in the last 50 years (Keel and Klump 2003).

Treatment

Treatment Goals
The goals of the treatment of bulimia nervosa are straightforward. The binge-eating and inappropriate compensatory behaviors should cease, and self-esteem should become more appropriately based on factors other than shape and weight.

The power struggles that often complicate the treatment process in anorexia nervosa occur much less frequently in the treatment of patients with bulimia nervosa. This is largely because the critical behavioral disturbances, binge-eating and purging, are less ego-syntonic and are more distressing to these patients. Most bulimia nervosa patients who pursue treatment agree with the primary treatment goals and wish to give up the core behavioral features of their illness.

Psychosocial Treatments
The treatment of bulimia nervosa has received considerable attention in recent years, and the efficacies of both psychotherapy and medication have been explored in numerous controlled studies (Figure 78–8). The form of psychotherapy that has been examined most intensively is cognitive-behavioral therapy, modeled on the therapy of the same type for depression (Fairburn 2002). Cognitive-behavioral therapy for bulimia nervosa concentrates on the distorted ideas about weight and shape, on the rigid rules regarding food consumption and the pressure to diet, and on the events that trigger episodes of binge-eating. The therapy is focused and highly structured and is usually conducted in 3–6 months. Approximately 25–50% of patients with bulimia nervosa achieve abstinence from binge-eating and purging during a course of cognitive-behavioral therapy, and in most, this improvement appears to be sustained. The most common form of cognitive-behavioral therapy is individual treatment, although it can be given in either individual or group format. The effect of cognitive-behavioral therapy is greater than that of supportive psychotherapy and interpersonal therapy, indicating that cognitive-behavioral therapy should be the treatment of choice for bulimia nervosa.
Somatic Treatments

The other commonly used mode of treatment that has been examined in bulimia nervosa is the use of antidepressant medication (Zhu and Walsh 2002). This intervention was initially prompted by the high rates of depression among patients with bulimia nervosa and has now been tested in more than a dozen double-blind, placebo-controlled studies, using a wide variety of antidepressant medications. Active medication has been consistently found to be superior to placebo, and, although there have been no large “head-to-head” comparisons between different antidepressants, most antidepressants appear to possess roughly similar antibulimic potency (Figure 78–9). Fluoxetine at a dose of 60 mg/day is favored by many investigators because it has been studied in several large trials and appears to be at least as effective as, and better tolerated than, most other alternatives. It is notable that it has not been possible to link the effectiveness of antidepressant treatment for bulimia nervosa to the pretreatment level of depression. Depressed and nondepressed patients with bulimia nervosa respond equally well in terms of their eating behavior to antidepressant medication.

Although antidepressant medication is clearly superior to placebo in the treatment of bulimia nervosa, several studies suggest that a course of a single antidepressant medication is generally inferior to a course of cognitive-behavioral therapy. However, patients who fail to respond adequately to, or who relapse following a trial of, psychotherapy may still respond to antidepressant medication.

Treatment-Refractory Patients

Although psychotherapy and antidepressant medication are effective interventions for many patients with bulimia nervosa, some individuals have little or no response. There is no clearly established algorithm for the treatment of such refractory patients. Alternative interventions that may prove useful include other forms of psychotherapy and other medications such as SNRIs, sibutramine, and topiramate; these pharmacological agents have not been extensively studied, but anecdotal reports and a few controlled studies suggest that they can be of benefit. Hospitalization should also be considered as a way to normalize eating behavior, at least temporarily, and perhaps to initiate a more effective outpatient treatment.

Special Factors Influencing Treatment

A major factor influencing the treatment of bulimia nervosa is the presence of other significant psychiatric or medical illness. For example, it can be difficult for individuals who are currently abusing drugs or alcohol to use the treatment methods described, and many psychiatrists suggest that the substance abuse needs to be addressed before the eating disorder can be effectively treated. Other examples include the treatment of individuals with bulimia nervosa and serious personality disturbance and those with insulin-dependent diabetes mellitus who “purge” by omitting insulin doses.
In treating such individuals, the psychiatrist must decide which of the multiple problems must be addressed first and may elect to tolerate a significant level of eating disorder to confront more pressing disturbances.

**BINGE-EATING DISORDER**

**Diagnosis**

**Definition and Diagnostic Features**

**History**

As noted earlier, binge-eating disorder is a proposed diagnostic category related to, but quite distinct from, bulimia nervosa. Individuals with binge-eating disorder, like individuals with bulimia nervosa, repeatedly engage in episodes of binge-eating but, unlike patients with bulimia nervosa, do not regularly utilize inappropriate compensatory behaviors. The phenomenon of binge-eating without purging among the obese was clearly described by Stunkard (1959), 20 years before bulimia nervosa was recognized. Yet binge-eating disorder has been the focus of sustained attention only recently.

**Definition**

Suggested diagnostic criteria for binge-eating disorder are included in an appendix of DSM-IV-TR, which provides criteria sets for further study. These criteria require recurrent episodes of binge-eating, which are defined just as for bulimia nervosa. The major difference from bulimia nervosa is that individuals with binge-eating disorder do not regularly utilize inappropriate compensatory behavior, although the precise meaning of “regularly” is not specified. Other differences from the definition of bulimia nervosa relate to the frequency of binge-eating: individuals with bulimia nervosa must binge-eat, on average, at least two times per week over the last 3 months, whereas individuals with binge-eating disorder must binge-eat at least 2 days per week over the last 6 months. A major reason for the difference in the criteria is that the end of a binge episode in bulimia nervosa is usually clearly marked by the occurrence of inappropriate compensatory behavior, like purging, whereas in binge-eating disorder, the end of a binge episode may be more difficult to identify precisely. The criteria attempt to deal with this definitional difficulty by requiring the frequency of binge-eating to be measured in terms of the number of days per week on which episodes occur, and, because of the potential difficulty in distinguishing “normal” overeating from binge-eating, to require a 6-month duration, rather than 3 months for bulimia nervosa. In addition, the suggested DSM-IV-TR criteria for binge-eating disorder require that individuals report behavioral evidence of a sense of loss of control over eating, such as eating large amounts of food when not physically hungry. Finally, while there is some evidence that individuals with binge-eating disorder tend to be more concerned about body image than individuals of similar weight, the criteria for binge-eating disorder require only that there is marked distress over the binge-eating. Thus, the criteria for binge-eating disorder do not require that self-evaluation be overly influenced by concerns regarding body weight and shape, as is required for bulimia nervosa.

**Assessment**

The assessment of individuals who may have binge-eating disorder parallels that of individuals who may have bulimia nervosa. It is important to obtain a clear understanding of daily food intake and of what the individual considers a binge. As in the assessment of bulimia nervosa, the interviewer should inquire about the use of purging and other inappropriate weight-control methods. Individuals who describe binge-eating disorder are likely to be obese, and it is important to obtain a history of changes in weight and of efforts to lose weight. The interviewer should also inquire about symptoms of mood disturbance and anxiety.

**Physical Examination and Laboratory Findings**

The salient general medical issue is that of obesity. Individuals with binge-eating disorder who are obese should be followed by a primary-care physician for assessment and treatment of the complications of obesity. There is no strong evidence at presence convincingly demonstrating that the behavioral disturbances characteristic of binge-eating disorder add to the physical risks of obesity. Whether the presence of binge-eating disorder affects the natural history of obesity is an intriguing but unanswered question.

**Epidemiology**

The prevalence of binge-eating disorder is much greater than that of anorexia nervosa or bulimia nervosa. A recent study suggests a lifetime prevalence of 3.5% among women and 2% among men (Hudson et al. 2007). The prevalence among obese individuals who attend weight loss clinics is substantially higher, and the frequency of binge-eating disorder increases with the degree of obesity. In contrast to anorexia nervosa and bulimia nervosa, individuals with binge-eating disorder are more likely to be men (the female-to-male ratio is roughly 1.5:1, compared to approximately 10:1 for anorexia nervosa and bulimia nervosa), from minority ethnic groups, and middle aged.

**Comorbidity Patterns**

Binge-eating disorder is frequently associated with symptoms of mood and anxiety disorder.

**Course**

As the recognition of binge-eating disorder is relatively recent, there is little definitive information about the natural history of this disorder. However, recent data suggest that the symptoms tend to be stable over time (Pope et al. 2006).

**Differential Diagnosis**

In theory, binge-eating disorder should be easy to recognize on the basis of patient self-report; the individual describes the frequent consumption of large amounts of food in a discrete period of time about which he or she feels distressed and unable to control. Difficulties arise, however, because of uncertainty about what precisely constitutes a “large amount of food,” especially for an obese individual, and regarding what constitutes a discrete period of time. Many individuals describe eating continuously during the day or evening, thereby consuming a large amount of food, but it is not clear whether such behavior is best viewed as binge-eating.
Clinical Vignette 1

When Ms. A was first evaluated for admission to an inpatient eating disorders program, she had been restricting her food intake for approximately 5 years and had been amenorrheic for 4 years. At the time of her admission, this 24-year-old, single, white woman weighed 71 lb at a height of 5 feet 1.5 inches. In 12th grade, Ms. A menstruated for the first time and also developed “very large” breasts. She had a difficult first year at college, where she gained to her maximum weight of 120 lb. The following year, Ms. A transferred to a smaller college, became a vegetarian “for ethical reasons,” and began to significantly restrict her food intake. She limited herself to a total of 700–800 cal/day, with a maximum of 200 calories per meal, and gradually lost weight in the next 5 years. Ms. A did not binge, vomit, abuse laxatives, or engage in excessive exercise. She considered herself to be “obsessed with calories” and observed a variety of rituals regarding food and food preparation (e.g., obsessively weighing her food).

Although Ms. A excelled academically, she had no close friends and had never been involved in a romantic relationship. She was quite close to her mother and sister and had always been dependent on her parents. After graduating (with honors) from college, Ms. A worked at a series of temporary jobs but was unemployed and living at home with her mother at the time of admission. She had been in outpatient psychotherapy with two different therapists during the previous 2 years. The first therapist did not address her eating disorder, and Ms. A continued to lose weight, from 90 to 80 lb. Although her second therapist confronted her about her anorexia nervosa and started her on desipramine at 20 mg/day for depressive symptoms, Ms. A continued to lose weight.

During her first 5-month hospitalization, Ms. A was treated with a multimodal program (behavioral weight gain protocol, individual and family therapy, fluoxetine at 60–80 mg for obsessive–compulsive traits, and depressive symptoms) and gained up to a weight of 98 lb. At discharge, she was maintaining her weight on food but remained concerned about her weight and was particularly frightened of reaching “the triple digits” (i.e., ≥100 lb). After leaving the hospital, Ms. A continued with outpatient psychotherapy and fluoxetine for several months. She was then seriously injured in a car accident and, during a prolonged convalescent period, discontinued treatment for her eating disorder. Ms. A remained unemployed, eventually moved in with her sister and her sister’s family, and gradually lost weight.

About 3.5 years after discharge, at the age of 27 years, Ms. A again sought inpatient treatment. At admission, she weighed 83 lb but still felt “fat.” During hospitalization, she steadily gained weight and was prescribed sertraline at 100 mg/day for feelings of low self-esteem, anxiety, and obsessional thinking. When she was discharged 5 months later, at a weight of 108 lb, she noted menstrual bleeding for the first time in more than 7 years. After leaving the hospital, Ms. A continued taking medication and began outpatient cognitive–behavioral psychotherapy. For the next year, she continued to struggle with eating and weight issues but managed to maintain her weight and successfully expand other aspects of her life by independently supporting herself with a full-time job, making new friends, and becoming involved in her first romantic relationship.

Clinical Vignette 2

When Ms. B, a 20-year-old white college student, was first evaluated for treatment at an outpatient eating disorders program, she had been binge-eating and purging for approximately 5 years. Each evening, she consumed large quantities of food, vomited three or four times, and took two to six laxatives. She also occasionally used herbal diuretics but had never abused diet pills or prescription diuretics. Ms. B’s weight was well within the normal range (106 lb at a height of 5 ft 2 inches). She was extremely concerned about her shape and weight, was afraid of becoming

Etiology and Pathophysiology

Little is known about the etiology of binge-eating disorder. Binge-eating disorder is clearly associated with obesity, but it is uncertain to what degree the binge-eating is a contributor to, and a consequence of, the obesity (Devlin, in press).

Treatment

Goals of Treatment

For most individuals with binge-eating disorder, there are three related goals. One is behavioral, to cease binge-eating. A second focuses on improving symptoms of mood and anxiety disturbance, which frequently are associated with binge-eating disorder. The third is weight loss for individuals who are also obese.

Somatic and Psychosocial Treatments

Treatment approaches to binge-eating disorder are currently under active study. There is good evidence that both psychological (e.g., CBT) and pharmacological (e.g., SSRI) interventions, which are effective for bulimia nervosa, are also useful in reducing the binge frequency of individuals with binge-eating disorder and in alleviating mood disturbance. However, it is not clear how helpful these approaches are in facilitating weight loss. Standard behavioral weight loss interventions employing caloric restriction also appear useful in helping patients to control binge-eating, as do other forms of psychotherapy, such as interpersonal psychotherapy. Pharmacological approaches to weight loss, such as sibutramine and orlistat, may be able to address both binge-eating and weight loss. Definitive information about the best treatment algorithm for binge-eating disorder has not yet been developed.

Individuals who meet the proposed definition of binge-eating disorder clearly have increased complaints of depression and anxiety, compared to individuals of similar weight without binge-eating disorder.

As noted above, the most difficult issue in the diagnostic assessment of binge-eating disorder is determining whether the eating pattern of concern to the individual meets the proposed definition of binge-eating. There are numerous varieties of unhealthy eating, such as the consumption of high fat foods, and the nosology of these patterns of eating is not well worked out.

Some individuals with atypical depression binge-eat when depressed; if the individual meets criteria for both a binge-eating disorder and an atypical depression, both diagnoses should be made.

Clinical Vignette 2

When Ms. B, a 20-year-old white college student, was first evaluated for treatment at an outpatient eating disorders program, she had been binge-eating and purging for approximately 5 years. Each evening, she consumed large quantities of food, vomited three or four times, and took two to six laxatives. She also occasionally used herbal diuretics but had never abused diet pills or prescription diuretics. Ms. B’s weight was well within the normal range (106 lb at a height of 5 ft 2 inches). She was extremely concerned about her shape and weight, was afraid of becoming...
fat, and wanted to weigh no more than 100 lb (“the double digits are nice too...maybe 90 lb, but I don’t think I could run at that weight”).

Ms. B always binged alone in her dormitory room while watching television and flipping through magazines. A typical binge might consist of two packages of cookies, a half-gallon of ice cream, one box of cereal, one can of spaghetti, one bag of pretzels, one can of soup, one package of fishsticks, one bag of candy, and six bagels with butter, eaten during a 3-4-hour period. She would vomit every hour or so, each time making room for more food. Throughout the day, she would severely restrict her food intake, usually eating nothing but fruit, salad, oatmeal, diet hot chocolate, coffee, and chewing gum. She was an avid cross-country runner, totaling about 50 miles per week, but denied running to compensate for eating binges.

Ms. B was raised on the East Coast by her parents, who were college graduates, and had an older brother. She had a history of always being thin, and when she was in the sixth grade, she weighed 75 lb at a height of 4 ft 9 inches. She began binge-eating and purging at the age of 16 years, after her father was hospitalized for a suicide attempt. She read many books about eating disorders, because she “wanted to be anorexic,” and within 2 months, she was binging and purging every day. She had periodically been treated for her eating disorder, both with individual psychotherapy and with 20 mg of fluoxetine; none of these treatments was significantly helpful. She was also hospitalized for 7 weeks at the age of 17 years and stopped binge-eating and purging, but anorexia nervosa developed. Her weight dropped to 95 lb, which was 80% of her ideal body weight. She had not menstruated since she began binge-eating and purging, and she did not menstruate again until she was 19 years old.

Other than her father’s depression, there was no family history of psychiatric illness or eating disorders. Ms. B had also had several major depressive episodes since she was 16 years old, during which she experienced depressed mood, loss of interest in her usual activities, tiredness, decreased concentration, and suicidal thoughts. She had never used drugs and drank only rarely.

Soon after she began a 4-month course of cognitive–behavioral therapy plus desipramine, 100 mg/day, Ms. B’s eating disorder improved substantially. By the time she completed treatment, she was still binge-eating and vomiting occasionally, but she felt much more in control of her bulimia. Her self-esteem was greatly improved, and she was more aware of distortions in her thoughts about her eating and body shape and weight. She was optimistic yet realistic about maintaining the gains she had achieved. Ms. B was prescribed desipramine for 3 months more, and then for the following 9 months, she was treated with fluoxetine, 30 mg/day, and met occasionally with another therapist. Ms. B continued to be much improved, but not entirely well, bingeeating and purging once or twice a month.

Clinicians, particularly psychiatrists and psychologists, need to master a general working knowledge of sleep and chronobiology, including the disorders of sleep and circadian rhythms, their clinical manifestations and differential diagnoses, and their clinical management. This chapter provides an overview of the most common topics in basic and clinical sciences of sleep.

PHENOMENOLOGY AND ORGANIZATION OF SLEEP

Physiological Regulation of Sleep and Wakefulness

Organization of Sleep
Sleep consists of two major states: (1) rapid eye movement (REM) sleep and (2) non-rapid eye movement (NREM) sleep, which alternate throughout the sleep period. In the adult, entry into sleep normally begins with NREM sleep and is followed after approximately 90 min by the first REM period. Thereafter, NREM sleep and REM sleep oscillate with a cycle length (the interval between onset of each NREM or REM period) of about 80–110 min (Figure 79–1). NREM sleep is predominant during the first third of the night while REM is predominant in the last third of the night.

On the basis of electroencephalographical (EEG) characteristics, NREM sleep in humans is further divided into stages: Stage 1, a brief transitional stage between wakefulness and sleep; Stage 2, which occupies the greatest amount of time during sleep; and Stages 3 and 4, often called delta sleep or slow wave sleep (SWS) because of the presence of characteristic high-amplitude slow EEG delta waves (Table 79–1). REM sleep is characterized by fast frequency EEG, REMs and inhibited muscle tone (atonia). Awakenings from REM sleep are commonly associated with reports of vivid dreaming, however, reports of dreams can also occur during NREM sleep, especially at sleep onset during stage 1 sleep.

Circadian Rhythm of Sleep and Wakefulness
Circadian rhythms are rhythms that fluctuate every 24 hr. The word 'circadian' comes from the Greek "circa" meaning “about” and “dies” meaning “day,” thus circadian rhythms take about a day, or 24 hr. The rest–activity or sleep–wake cycle is an example of a circadian rhythm (Table 79–2). Circadian rhythms are also seen in hormonal secretions, gastric activity, and core body temperature, just to name a few. An example of the interaction between different circadian systems is the relationship between core body temperature and the sleep/wake cycle. Sleep initiation is associated with a drop in core body temperature with the nadir in the early...
morning hr, around 3–4 AM, while awakening from sleep is associated with core body temperature rising.

Circadian rhythms can be characterized by three different measures: (a) cycle length (tau) (e.g., the time between two peaks of the 24-hr temperature curve); (b) amplitude (e.g., the difference between the minimum value of the cycle (nadir) and maximum value, for example, the difference between the lowest and highest points in the 24-hr temperature curve); and (c) phase position of the rhythm (acrophase) (e.g., the time of day when the peak of the rhythm occurred).

### Table 79–1: Commonly Used Terms in Human Sleep Studies

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Delta wave</td>
<td>EEG pattern conventionally defined as ≤ 75 mV, ≤ 0.5 Hz (or cycles per second) wave; the amplitude tends to decrease with normal aging</td>
</tr>
<tr>
<td>NREM sleep</td>
<td>Stages 1, 2, 3, and 4 sleep</td>
</tr>
<tr>
<td>Total sleep time</td>
<td>Time from onset of sleep to onset of REM sleep; declines from about 70–100 min in the 20s to 55–70 min in the elderly, short REM latency associated with narcolepsy, depression, and a variety of clinical conditions</td>
</tr>
<tr>
<td>REM latency</td>
<td>NREM plus REM sleep time</td>
</tr>
<tr>
<td>REM sleep</td>
<td>REM sleep; characterized by low-voltage, relatively fast frequency EEG, bursts of REMs, and loss of tone (atonia) in the major antigravity muscles; associated with dreaming</td>
</tr>
<tr>
<td>Sleep efficiency</td>
<td>Percentage of time in bed spent in sleep; usually above 90% in the young, falls somewhat with age</td>
</tr>
<tr>
<td>Sleep latency</td>
<td>Time from “lights out” to onset of sleep</td>
</tr>
<tr>
<td>Stage 1 sleep</td>
<td>A brief transitional state of sleep between wakefulness and sleep, characterized by low-voltage, mixed-frequency EEG, and slow eye movements; about 5% of total sleep time</td>
</tr>
<tr>
<td>Stage 2 sleep</td>
<td>Characterized by K complexes and sleep spindles (12–14 per cycle rhythms) in the EEG; usually about 45–75% of total sleep time</td>
</tr>
<tr>
<td>Stages 3 and 4 sleep</td>
<td>Sometimes referred to as delta or slow wave sleep (SWS), based on amount of sleep delta waves in EEG, 20–50% of an epoch (i.e., 30 or 60 s) for Stage 3, more than 50% for Stage 4; amount per night declining from about 20–25% of total sleep time in the teens to nearly zero in the elderly</td>
</tr>
<tr>
<td>WASO</td>
<td>Wake time after sleep onset</td>
</tr>
<tr>
<td>REM density</td>
<td>A measure of amount of ocular activity per minute of REM sleep</td>
</tr>

</table>

### Table 79–2: Commonly Used Terms in Chronobiology

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acrophase</td>
<td>The time at which the maximal point of a circadian rhythm occurs, i.e., maximal secretion of cortisol normally occurs at midmorning in humans.</td>
</tr>
<tr>
<td>Circadian rhythm</td>
<td>Refers to biological rhythms having a cycle length of about 24 hr, derived from Latin <em>circa dies</em>, “about 1 d”; examples include the sleep–wake cycle in humans, temperature, cortisol, and psychological variation in the 24-hr day; characterized by exact cycle length (tau), amplitude, and phase position.</td>
</tr>
<tr>
<td>Constant routine</td>
<td>An experimental method used to estimate amplitude and phase position of circadian temperature and neuroendocrine rhythms; the subject remains awake for about 36 hr under dim light, with head elevated slightly, eating frequent equal-calorie meals, while blood samples are withdrawn unobtrusively every 20–30 min and rectal temperature is measured about once a minute.</td>
</tr>
<tr>
<td>Dim light MT onset (DLMO)</td>
<td>An experimental method for estimating the phase of MT onset; under dim light conditions starting in late afternoon, blood samples are withdrawn every 20–30 min to determine when MT secretion begins.</td>
</tr>
<tr>
<td>Nadir</td>
<td>Time when the minimal point of a circadian rhythm occurs.</td>
</tr>
<tr>
<td>Phase position</td>
<td>Temporal relationship between rhythms or between one rhythm and the environment; e.g., maximal daily temperature peak (acrophase) usually occurs in the late afternoon.</td>
</tr>
<tr>
<td>Phase-advanced rhythm</td>
<td>Phase position of biological rhythm occurs earlier than reference, i.e., the patient retires and arises early.</td>
</tr>
<tr>
<td>Phase-delayed rhythm</td>
<td>Phase position of biological rhythm occurs later than reference, i.e., the patient retires and arises late.</td>
</tr>
<tr>
<td>Phase-response curve</td>
<td>Graph showing the magnitude and direction of change in phase position of circadian rhythm depending upon timing of Zeitgeber with reference to the endogenous oscillator.</td>
</tr>
<tr>
<td>Tau</td>
<td>Cycle length, e.g., from one acrophase to the next.</td>
</tr>
<tr>
<td>Zeitgebers</td>
<td>Time cues, such as social activities, meals, and bright lights, that influence phase position of rhythm.</td>
</tr>
</tbody>
</table>
The propensity for sleep and wakefulness varies in a circadian fashion, at least after infancy, and is modulated in part by one or more biological clocks. The suprachiasmatic nucleus (SCN) in the anterior hypothalamus plays a decisive role in the regulation of most circadian rhythms in humans and animals. The endogenous activity rhythms of the SCN are synchronized with the environment, primarily by ambient light. Information regarding light reaching the retina is conveyed to the SCN directly through the retinohypothalamic tract and indirectly through the intergeniculate leaflet of the lateral geniculate body. Changes in light intensity, especially at dawn and dusk, are particularly important in synchronizing endogenous oscillators controlling rhythms of sleep–wake, cortisol, melatonin (MT), and core body temperature with one another and with the outside world.

If humans are allowed to choose their sleep–wake cycles in the absence of time cues such as daily light–dark signals or clocks, they usually show, as most mammalian species do, a sleep–wake cycle longer than 24 hr. The self-selected rest–activity cycle is typically slightly longer, implying that neurons within the SCN have an inherent rhythmicity of approximately 24.2 hr. Subjects in a time-free environment are said to “free-run” because endogenous processes, such as a circadian oscillator, rather than environmental cues, determine their sleep–wake, endocrine, and other rhythms.

Exposure to light and darkness at appropriate times of the day can shift the circadian rhythms (Czeisler et al. 1989). Bright light at the beginning of the subjective evening in conjunction with dark during the subjective morning delays and resets the phase position of the temperature, cortisol, MT, and sleep–wake rhythms; dark in the subjective evening and bright light in the subjective morning have the opposite effect (i.e., advancing the rhythm). The magnitude and direction of the changes induced by bright light or other zeitgebers (“timegivers”) at any particular time form the phase-response curve (Figure 79–2).

Animal research has demonstrated that lesions of the SCN abolish circadian rhythms of temperature, cortisol secretion, eating, drinking, or sleep–wakefulness. Sleep and wakefulness, for example, appear in brief bouts throughout the 24-hr day. Total sleep time, however, may increase under these circumstances.

**Homeostatic Regulation of Sleep–Wakefulness**

Common experience suggests that the longer one is awake, the sleepier one feels. Conversely, sleep reverses sleepiness and other consequences of wakefulness. Thus, sleep serves a homeostatic function; it is a time of rest and restoration that overcomes the “ravages of wakefulness” (Daan et al. 1984). Consistent with this hypothesis, sleep deprivation usually decreases sleep latency and increases sleep efficiency and the amount of SWS on recovery nights.

**Figure 79–2**. The phase-response curve in the hamster, demonstrating the magnitude and direction of phase-shifting properties of bright light, depending on when the light is presented with relationship to circadian time.

The precise regulation of sleep and wakefulness remains an area of intense investigation and theory. Two current theories of sleep–wake regulation include the two-process model (Daan et al. 1984) and the opponent process model (Edgar et al. 1993). The first postulates that sleep and wakefulness are regulated by a circadian process (Process C), which sets the circadian thresholds for sleep and wakefulness, and a homeostatic process (Process S), in which sleep propensity builds up with wakefulness and dissipates during NREM sleep, especially SWS. The opponent process model postulates that the SCN promotes alertness and that duration of wakefulness facilitates sleep.

**Normal Age-Related Changes in Sleep and Wakefulness**

The newborn spends nearly 50% of total sleep time in REM sleep. Because infants may sleep up to 16 hr a day, the infant may spend 8 hr in REM sleep per day. Newborns display a polyphasic sleep–wake pattern, with short bouts of sleep and wakefulness throughout the 24-hr day, until several months of age when the child eventually sleeps through the night. Daytime napping, however, often persists until the age of 4–6 years. SWS increases in the early years. Maximal “depth” of sleep may occur during the prepubertal period, when children are often difficult to awaken at night. Adolescents often still need at least 10 hr of sleep. Yet, during adolescence, Stages 3 and 4 sleep decline and daytime sleepiness increases, partially in association with the normal Tanner stages of pubertal development. Teenagers are also phase delayed which means that they may not get sleepy until the early morning hours (e.g., 2–3 AM) and do not naturally wake up until the later morning hours. Early school-start times and social pressures may produce mild sleep deprivation during weekdays, with some catch-up on weekends.

As adults enter middle age and old age, sleep often becomes more shallow, fragmented, and variable in duration and circadian timing compared with that of young adults. Stages 1 and 2 and the amount of time spent awake during the night tend to increase; REM latency and SWS decline. In a meta-analysis of 65 studies, examining over 3500 participants aged 5–102 years old, Ohayon concluded that most age-related sleep changes occur in early and mid-years of human life span, and in healthy older...
and McCarley 1990) (Figure 79–3). The isolated brain stem REM sleep cycle is regulated within the brain stem (Steriade 1993). The alternating between the states of sleep, REM and NREM.

The night.

“sleep debt” that has accumulated during hours of wakefulness. As the sun rises, when alertness is required, cells in the TMN are released from inhibitory control, leading to REM.

The model is based on observed reciprocal interactions between two hypothalamic areas, the ventrolateral preoptic area (VLPO) and the tuberomammillary nucleus (TMN). The sun rises, when alertness is required, cells in the TMN are released from inhibitory control, leading to REM.

Caffeine probably promotes alertness by blocking the adenosine A1 receptor. Histamine and glutamine also appear to play important roles in promoting alertness and brain activation. Of particular importance to psychiatry, acetylcholine, released from neurons originating in the dorsal tegmentum, induces REM sleep and cortical activation. Serotonin and norepinephrine, on the other hand, inhibit REM sleep, possibly by inhibition of cholinergic neurons responsible for REM sleep. These physiological mechanisms may be involved in both depression and schizophrenia associated with depression and other neuropsychiatric disorders, such as short REM latency (see below). For example, depression may be associated with a functional serotonin deficiency. The suppression of REM sleep during treatment with antidepressants may reflect either enhanced serotoninergic or noradrenergic neurotransmission or anticholinergic effects.

Sleep Disorders

This chapter attempts to provide a framework for psychiatrists and other mental health specialists to use in understanding the multiple causes of the sleep disorders, their diagnostic evaluation, and their treatment. Sleep disorders can be divided into four major categories: (1) insomnias, disorders associated with complaints of insufficient, disturbed, or nonrestorative sleep, (2) hypersomnias, disorders of excessive sleepiness, (3) disturbances of the circadian sleep–wake cycle, and (4) parasomnias, abnormal behaviors or abnormal physiological events in sleep. By definition, the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) limits itself to chronic disorders (at least 1 month in duration) (American Psychiatric Association 2000). On the other hand, the International Classification of Sleep Disorders (ICSD) includes sleep disorders of short-term and intermediate duration, which in fact are more common than chronic disorders (American Academy of Sleep Medicine 2005).
General Approach to the Patient with a Sleep Disorder

Disorders of sleep and wakefulness are common. Insomnia complaints are reported by about one-third of adult Americans during a 1-year period (Ancoli-Israel and Roth 1999); clinically significant obstructive sleep apnea may be seen in as many as 10% of working, middle-aged men (Young et al. 1993) and sleepiness is an under-recognized cause of dysphoria, automobile accidents, and mismanagement of patients by sleep-deprived physicians. All physicians hear complaints of sleep problems. Psychiatrists may be even more likely than other medical specialists to receive these complaints. Of particular importance for mental disorders, prospective epidemiological studies suggest that persistent complaints of either insomnia (Ford and Kamerow 1989, Livingston et al. 1993) or hypersomnia (Ford and Kamerow 1989) are risk factors for the later onset of depression, anxiety disorders, and substance abuse.

Clinicians treating patients with sleep complaints must have a diagnostic framework with which to obtain the information needed about both the patient as a person and his or her disorder. Two issues are particularly important: (i) How long has the patient had the sleep complaint? Transient insomnia and short-term insomnia, for example, usually occur in persons undergoing acute stress or other disruptions, such as admission to a hospital, jet lag, bereavement, or change in medications. Chronic sleep disorders, on the other hand, are often multidetermined and multifaceted. (ii) Does the patient suffer from any preexisting or comorbid disorders? Does another condition cause the sleep complaint, modify a sleep complaint, or affect possible treatments?

A detailed history of the complaint and attendant symptoms must be obtained (Tables 79–3 and 79–4). Special attention should be given to the timing of sleep and wakefulness; quantitative subjective measures of sleep and wakefulness, and when appropriate, qualitative measures of sleep; abnormal sleep-related behaviors; respiratory difficulties; medications or other substances affecting sleep, wakefulness, or arousal; expectations, concerns, attitudes about sleep, and efforts used by the patient to control symptoms; and the sleep–wake environment.

One approach to the differential diagnosis of persistent sleep disorders is suggested in the algorithm in Figure 79–4. First, determine whether the sleep complaint is comorbid with a medical, psychiatric, or substance use disorder. Second, consider the role of circadian rhythm disturbances and sleep disorders associated with abnormal events occurring predominantly during sleep (such as periodic limb movements, REM behavior disorder or parasomnias). Finally, evaluate in greater detail complaints of insomnia (difficulty initiating or maintaining sleep) and
excessive sleepiness. The possible role of sleep apnea as a disruptive factor in sleep continuity should be considered even if the principal complaint is one of insomnia.

**Role of the Sleep Laboratory in Clinical Sleep Disorders**

Clinicians can successfully diagnose most sleep disorders by traditional clinical methods. Referral to a specialized sleep disorders center, however, should be considered in patients with symptoms of intractable insomnia or persistent excessive daytime sleepiness (EDS). Patients suspected of primary sleep disorders such as narcolepsy, RBD, sleep apnea, or periodic limb movements in sleep (PLMS) would also benefit from a referral to a sleep specialist. Specialists in sleep disorders medicine will evaluate the patient and, if necessary, arrange for sleep laboratory or ambulatory diagnostic procedures.

The most frequently utilized sleep laboratory evaluation is polysomnography (PSG), which typically records the EEG activity, eye movements with the electrooculogram (EOG), and muscle tone with the electromyogram (EMG) from the chin (submental) and other muscles. These measures are used to determine sleep stages. To evaluate sleep-related respiration and cardiovascular function, measures are made of nasal and oral air flow with a thermistor or cannula; of sounds of breathing and snoring with a small microphone on the neck or near the mouth; of respiratory movements of the chest and abdominal walls; of heart rate with the electrocardiogram; and of blood-oxygen saturation with finger oximetry. To evaluate PLMS, an EMG from the shin (anterior tibial) muscles is obtained. Other more specialized tests include intraesophageal pressures, which increase during the upper airway resistance syndrome if respiration is impeded and measures of gastroesophageal pH.

Daytime sleepiness can be evaluated in the sleep laboratory with the Multiple Sleep Latency Test (MSLT), which measures sleep latency during opportunities for napping during the day or with the Maintenance of Wakefulness Test (MWT), which measures the capacity to remain awake (see Table 79–4). Both tests consist of four or five recordings, typically obtained at 2-hr intervals over the course of a day. In the MSLT, the patient is asked to fall asleep while lying in bed in a dark, quiet room. In the MWT, the patient is asked to remain awake while sitting upright in a dimly lit room. In both tests, EEG measures are used to determine the appearance of sleep. In addition, subjective sleepiness can be assessed by questionnaires. One of the most widely used scales is the Epworth Sleepiness Scale (Johns 1994), in which the subject rates himself or herself from 0 (not sleepy) to 3 (very sleepy) in eight situations, for example, sitting quietly in a car, sitting and talking to someone, etc.

**Table 79–3** Office Evaluation of Chronic Sleep Complaints

| Detailed history and review of the sleep complaint: predisposing, precipitating, and perpetuating factors |
| Review of difficulties falling asleep, maintaining sleep, and awakening early |
| Timing of sleep and wakefulness in the 24-hr day |
| Evidence of EDS and fatigue |
| Bedtime routines, sleep setting, physical security, preoccupations, anxiety, beliefs about sleep and sleep loss, fears about consequences of sleep loss |
| Medical and neurological history and physical examination, routine laboratory examinations: look for obesity, short fat neck, enlarged tonsils, narrow upper oral airway, foreshortened jaw (retroglossia), and hypertension |
| Psychiatric history and examination |
| Use of prescription and nonprescription medications, alcohol, stimulants, caffeine, toxins, insecticides, and other substances |
| Evidence of sleep-related breathing disorders: snoring, orthopenia, dyspnea, headaches, falling out of bed, nocturia |
| Abnormal movements or behaviors associated with sleep disorders: “jerky legs,” leg movements, myoclonus, restless legs, leg cramps, nightmares, enuresis, sleepwalking, epilepsy, bruxism, sleep paralysis, hypnagogic hallucinations, cataplexy, night sweats, and so on |
| Social and occupational history, marital status, living conditions, financial and security concerns, physical activity |
| Sleep-wake diary for 2 weeks |
| Interview with bed partners or persons who observe patient during sleep |

**Table 79–4** Selected Disorders and Terms Used in Clinical Sleep Disorders Medicine

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Apnea index</td>
<td>Number of apneic events per hour of sleep; usually considered pathological if ≥ 5.</td>
</tr>
<tr>
<td>Cataplexy</td>
<td>Sudden, brief loss of muscle tone in the waking stage; usually triggered by emotional arousal (laughing, anger, surprise), involving either a few muscle groups (i.e., facial) or most of major antigravity muscles of the body; may be related to muscle atonia normally occurring during REM sleep; is associated with narcolepsy.</td>
</tr>
<tr>
<td>Hypopnea</td>
<td>50% or more reduction in respiratory depth for 10 s or more during sleep</td>
</tr>
<tr>
<td>MSLT</td>
<td>An objective method for determining daytime sleepiness; sleep latency and REM latency are determined for four or five naps (i.e., a 20-min opportunity to sleep every 2 hr between 10 am and 6 pm); normal mean values are above 15 min.</td>
</tr>
<tr>
<td>MWT</td>
<td>An objective method for determining daytime sleepiness; which measures the capacity to remain awake</td>
</tr>

patients may be genetically predisposed to insomnia, with reduced homeostatic sleep drive. Other predisposing factors, such as personality traits (e.g., anxious, obsessional, depressive, and avoidant personality traits), also put individuals at risk for developing insomnia. Precipitating and perpetuating factors can result in transient insomnia becoming chronic.

**Assessment of Insomnia**

Diagnosis and treatment of chronic insomnia are often challenging and difficult. PSG is rarely indicated as part of the routine evaluation of the insomnia patient. Both the clinician and the patient must be forbearing and realistic as they jointly explore the evolution, causes, manifestations,
and ramifications of the sleep complaint. Simple answers and simple solutions are rare. Even if insomnia is initially precipitated by a single event or condition, chronic insomniacs is usually maintained by various predisposing and perpetuating factors. For example, a business woman in her early thirties had insomnia during a period of intense stress in her business, but it continued long after the stress had been satisfactorily resolved. Factors that contributed to chronicity included her lifelong somewhat obsessive, anxious personality structure and, after the onset of her insomnia, her gradually escalating concerns about her insomnia; these resulted in advanced sleep phase as she tried to spend more time in bed for “rest” and use of wine at bedtime to sleep. Her use of wine at bedtime absolutely contributed to her fragmented sleep. Properly sorting out and dealing with these factors led to resolution of her complaints.

Epidemiology
In general surveys of the prevalence of insomnia in the population, about 1 in 12 people reported “insomnia” during the previous year, about 1 in 6 described it as “serious,” and about 1 in 12 called it “chronic” (Ancoli-Israel and Roth 1999). The rates of insomnia are higher in women than in men, in the elderly than in the young, and in the lower than in the higher socioeconomic classes. In a survey conducted by the Gallup Poll for the National Sleep Foundation (Ancoli-Israel and Roth 1999, Roth and Ancoli-Israel 1999), the most common complaint of insomniacs was waking up feeling drowsy rather than specific complaints about sleep, implying that the sleepiness insomniacs experience could be associated with some morbidity. Compared with transient insomniacs or normal control subjects, chronic insomniacs reported greater difficulty enjoying family and social relationships, greater difficulty concentrating, more problems with memory, greater frequency of falling asleep while visiting friends, and more automobile accidents due to sleepiness. Nevertheless, only about 5% of patients with chronic insomnia ever sought medical attention specifically for insomnia. Only a minority of patients have ever used prescription sleeping pills. On the other hand, most psychiatrists do not routinely inquire about difficulties with sleep and wakefulness. If these patients with chronic or serious insomnia are to be helped, psychiatrists must be proactive and ask specific questions about sleep and its disorders.

Comorbidity Patterns
A recent National Institutes of Health (NIH) (National Institutes of Health 2005) State-of-the-Science conference on insomnia focused extensively on comorbid insomnia, emphasizing the need to recognize how medical and psychiatric conditions interact and impact on insomnia complaints. The concept of comorbidity recognizes that two pathological states, for example, depression and insomnia, likely exist concurrently and will influence each other’s course. Treating one does not mean necessarily that the other will improve; on the other hand, exacerbation in one may make the comorbid condition worse.

Insomnia Comorbid with Psychiatric Disorders
As noted above, the DSM-IV-TR classification system has a specific category for Primary Insomnia, a disorder characterized as not being related to or caused by another sleep, mental, medical disorder or affects of a medication. Breathing-Related Sleep Disorder (BRSD) is a separate diagnosis, and is recognized as presenting at times with insomnia complaints.

A number of recent changes in the DSM-IV-TR have increased the utility of this instrument for the diagnosis of sleep disorders. These include codes for Insomnia due to specified Axis I and Axis II Disorder (e.g., Major Depressive Disorder and Generalized Anxiety Disorder) and Hypersomnia due to specified Axis I and Axis II Disorder (e.g., Major Depressive Disorder and Dysthymic Disorder). Also included is a code for Sleep Disorder due to a specified General Medical Condition, with the capacity to code this as Insomnia, a Hypersomnia, a Parasomnia, or a Mixed Type Disorder.

Circadian Rhythm Sleep Disorder is given a separate category, with separate coding for Delayed Sleep Phase, Jet Lag, and Shift Work Types. Substance-Induced Sleep Disorders also have specific codes based on the inducing agent (i.e., alcohol, opioids, amphetamines, etc.).

Although there is a specific category for “Primary Insomnia”, there is no formal category for “Secondary Insomnia”. Instead, many diagnoses reside within the broad “Dysomnia Not Otherwise Specified” section for disturbances such as Restless Leg Syndrome (RLS) and Insomnia of Environmental Origin.

Subjective and objective disturbances of sleep are common features of many psychiatric disorders. Complaints may be of insomnia or hypersomnia, parasomnias (such as nightmares, night terrors, and nocturnal panic attacks), and circadian rhythm disturbances (early morning awakening). Before assuming that a significant sleep complaint invariably

---

**DSM-IV-TR Criteria**

**Primary Insomnia**

A. The predominant complaint is difficulty initiating or maintaining sleep, or nonrestorative sleep, for at least 1 month.

B. The sleep disturbance (or associated daytime fatigue) causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The sleep disturbance does not occur exclusively during the course of narcolepsy, breathing-related sleep disorder, circadian rhythm sleep disorder, or a parasomnia.

D. The disturbance does not occur exclusively during the course of another mental disorder (e.g., major depressive disorder, generalized anxiety disorder, a delirium).

E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

---

signals a psychiatric diagnosis, mental health specialists should go through a careful differential diagnostic procedure to rule out medical, pharmacological, or other causes. Even if the sleep complaint is primarily related to an underlying psychiatric disorder, sleep disorders in the mentally ill may be exacerbated by many other factors, such as increasing age; comorbid psychiatric, sleep, and medical diagnoses; alcohol and substance abuse; effects of psychotropic or other medications; use of caffeinated beverages, nicotine, or other substances; lifestyle; past episodes of psychiatric illness (persisting “scars”); and cognitive, conditioned, and coping characteristics such as anticipatory anxiety about sleep as bedtime nears. Some features of these sleep disorders may persist during periods of clinical remission of the psychiatric disorder and may be influenced by genetic factors. Finally, even if the sleep complaint is precipitated by a nonpsychiatric factor, psychiatric and psychosocial skills may be useful in ferreting out predisposing and perpetuating factors involved in chronic sleep complaints.

Although signs and symptoms of sleep disturbance are common in most psychiatric disorders, an additional diagnosis of insomnia or hypersomnia related to another mental disorder is made according to DSM-IV-TR criteria only when the sleep disturbance is a predominant complaint and is sufficiently severe to warrant independent clinical attention. Many of the patients with this type of sleep disorder diagnosis focus on the sleep complaints to the exclusion of other symptoms related to the primary psychiatric disorder. For example, they may seek professional help with complaints of insomnia or oversleeping when they should be at work, excessive fatigue, or desire for sleeping pills, but initially, they minimize or strongly deny signs and symptoms related to poor mood, anxiety, obsessive ruminations, alcohol abuse, or a personality disorder.

**Sleep Disturbances in Psychiatric Disorders: “Chicken or Egg?”**

Chronic sleep disturbances may be risk factors for certain vulnerable individuals. For example, several longitudinal epidemiological studies reported that a persistent complaint of insomnia for a year was also a risk factor for the later onset of major depressive disorder, anxiety disorder, and substance abuse, for example, (Ford and Kamerow 1989, Livingston et al. 1993). One of these studies also assessed persistent hypersomnia and found that this complaint was a risk factor. Thus, specific sleep characteristics may predispose to, or be a risk factor for, later development of psychiatric or substance abuse disorders. Again, the complaint of chronic insomnia or hypersomnia or normal short sleep cannot always be equated with objective sleep abnormalities, but it should at least alert the psychiatrist to the possibility that the patient deserves careful monitoring for a time.

Sleep disruption may be particularly harmful to some persons, for example, bipolar disorder patients, whether euthymic or depressed, in whom sleep deprivation may precipitate a manic episode (Wehr 1992). Mania is not uncommon with jet lag or work-related sleep deprivation in bipolar disorder patients. Behavioral and apparent personality changes with sleep deprivation are probably common but more often ignored in everyday life. The irritability of sleep-deprived children is known to most parents; and who of us has not had a “bad day” after a “bad night”? Thus, the role of subjective insomnia and sleep loss in the prediction and prevention of mood disorders deserves further attention from psychiatrists and researchers.

Whereas insomnia is probably the most common sleep complaint in most psychiatric disorders, hypersomnia is not an infrequent complaint, especially in association with the following: bipolar mood disorder during depressed periods; major depressive disorder with atypical features (i.e., hypersomnia, hyperphagic patients with “leaden paralysis” and loss of energy); seasonal (winter) depression; stimulant abusers during withdrawal; some patients with personality disorders; and patients who are heavily sedated with anxiolytic, antipsychotic, or antidepressant medications, among other disorders.

More studies of sleep and sleep-related phenomenology have been conducted in depression than in any other disorder (Figure 79–5). Despite the common clinical impression that early morning wakefulness is a predominant symptom in depression, most of the objective measures in recent years have implicated abnormalities occurring at sleep onset and during the first NREM and REM periods: prolonged sleep latency; reduced Stages 3 and 4 sleep; increased duration and REM density of the first REM period; and associated neuroendocrine abnormalities, abnormalities in the HPA axis including increases in CRH and cortisol secretion, and abnormal dexamethasone suppression tests (Nestler et al. 2002). Furthermore, some studies have suggested that short REM latency or reduced delta sleep ratio (amount of delta waves in first NREM periods compared with second NREM periods) may predict relapse in depressed patients. Some of these sleep-related abnormalities appear to persist during periods of clinical remission, such as short REM latency, loss of Stages 3 and 4 sleep, and blunted nocturnal growth hormone release. Genetic factors may influence some of these measures, including short REM latency.

Given the prevalence of sleep disturbance in depression, one puzzle is the well-established observation that sleep deprivation and some other manipulations of sleep have antidepressant effects in about half of depressed patients. Total and partial sleep deprivation for one night has the best-documented benefits but, unfortunately, has not gained widespread clinical utility because most patients usually wake up depressed again after napping or sleeping. One exception may be premenstrual depression: partial sleep deprivation for one night at the onset of symptoms often aborts the symptoms for that month.

Even though the polygraphic sleep findings in depression do not appear to be diagnostically specific, they remain among the best-documented biological abnormalities of any psychiatric disorder at this time. One challenge is to understand their pathophysiological mechanism. Because of the shallow, fragmented sleep and response to sleep deprivation, the sleep of patients with depression has been described as “overaroused.” For instance, the antidepressant response of sleep deprivation may “dampen down” an overly aroused limbic system in a subgroup of patients. Several studies have shown that responders to sleep deprivation differ from nonresponders at baseline assessment before sleep deprivation by having a higher level of metabolic activity in the cingulate gyrus and that this overactivity
approaches normality with clinical improvement (Ebert et al. 1994, Gillin et al. 2001).

**Treatment of Chronic Insomnia**

Clinical management of insomnia is multidimensional, requiring behavioral and pharmacological approaches.

**Behavioral Treatments**

Treatment of insomnia should, insofar as possible, be directed at identifiable causes, or those factors that perpetuate the disorders, such as temperament and lifestyle, ineffective coping and defense mechanisms, inappropriate use of alcohol or other substances, maladaptive sleep–wake schedules, and excessive worry about poor sleep. The harder these individuals try to sleep, the more elusive sleep becomes. They keep themselves awake by their apprehensions: “If I don’t get to sleep right now, I won’t be able to function tomorrow.”

Table 79–5 lists the more common behavioral treatments. The most effective treatment for insomnia is cognitive–behavioral therapy (CBT), which as the name implies, is made up of both a cognitive and a behavioral component. The cognitive component reduces autonomic and cognitive arousal, targets maladaptive coping, challenges dysfunctional beliefs about sleep (e.g., “I must sleep 8 hr”), corrects unrealistic expectations (e.g., “I should never wake up at night”), reappraises perceptions of the insomnia consequences (e.g., “I can’t work without 8 hr of sleep”), and recognizes maladaptive thoughts and associated catastrophic ideas that foster insomnia. Some of the common worries and catastrophic thoughts that patients with insomnia endorse include: “If I don’t sleep well tonight I will...do poorly at work and get fired, be irritable with my husband who will divorce me, get sick and die, look unattractive and people will not want to be in my presence.” The CBT challenges

black and white thinking, such as words like “always” (sleep poorly) or “never” (perform well) (Perlis et al. 2005).

The behavioral component of CBT identifies patient-specific perpetuating factors of insomnia and eliminates them behaviorally (e.g., use of alcohol to fall asleep, watching scary movies before going to bed). The patient is encouraged to create a relaxing before bedtime ritual (e.g., diary writing, hot bath, meditation) and not to try to compensate for a poor night’s sleep by spending more time in bed in the morning or napping (Perlis et al. 2005). The behavioral component targets maladaptive coping (e.g., staying in bed for 12 hr), eliminates sleep incompatible behaviors (e.g., poor sleep hygiene), regularizes the sleep schedule, and educates patients about healthier sleep practices. The two behavioral treatments most commonly applied to accomplish these goals are stimulus-control therapy and sleep restriction therapy (Bootzin and Nicassio 1978; Morin et al. 1994; Spielman et al. 1987). The aim of stimulus control therapy is to break the negative associations of being in bed unable to sleep (Table 79–6). It is especially helpful for patients with sleep-onset insomnia and prolonged awakenings. Sleep restriction therapy (Table 79–7) is based on the observation that more time spent in bed leads to more fragmented sleep. Both therapies may take 3–4 weeks or longer to be effective.

CBT is effective for 70–80% of insomnia patients. It significantly reduces several measures of insomnia, including sleep-onset latency and wake-after-sleep onset. Aside from the clinically measurable changes, CBT enables many patients to regain a feeling of control over their sleep, thereby reducing the emotional distress that sleep disturbances cause (Morin et al. 1994).

### Table 79–7  Sleep Restriction Therapy
- Stay in bed for the amount of time you think you sleep each night, plus 15 min.
- Get up at the same time each day.
- Do not nap during the day.
- When sleep efficiency is 85% (i.e., sleeping for 85% of the time in bed), go to bed 15 min earlier.
- Repeat this process until you are sleeping for 8 hr or the desired amount of time.
- Example: if you report sleeping only 5 hr a night and you normally get up at 6 AM, you are allowed to be in bed from 12:45 AM until 6 AM.

### Table 79–6  Sleep Hygiene and Stimulus Control Rules
- Curtail time spent awake while in bed.
- Go to bed only when sleepy.
- Do not remain in bed for more than 20–30 min while awake.
- Get up at the same time each day.
- Avoid looking at the bedroom clock.
- Avoid caffeine, alcohol, and tobacco near bedtime.
- Exercise during the morning or afternoon.
- Eat a light snack before bed.
- Adjust sleeping environment for optimal temperature, sound, and darkness.
- Do not worry right before and in bed. Use the bed for sleeping.
- Do not nap during the day.

### Pharmacological Treatment

The ideal sleeping pill would shorten latency to sleep; maintain normal physiological sleep all night without blocking normal behavioral responses to the crying baby or the alarm clock; leave neither hangover nor withdrawal effects the next day; and be devoid of tolerance and side effects such as impairment of breathing, cognition, ambulation, and coordination. Furthermore, sleeping pills should not be habit-forming or addictive. Unfortunately, the ideal sleeping pill has yet to be developed.

There are numerous nonbehavioral, options for the treatment of insomnia. These include dietary supplements and herbal preparations, the over-the-counter medications, benzodiazepines receptor agonists (BzRAs) (Tables 79–8 and 79–9) and a MT receptor agonist (Table 79–9). In the NIH State-of-the-Science conference on insomnia (National Institutes of Health 2005), the panel concluded that there was very little evidence that dietary supplements and herbal remedies showed any benefit beyond placebo and that although MT was safe, there was little evidence for efficacy in the treatment of insomnia.

The NIH (National Institutes of Health 2005) also concluded that not only was there no systematic evidence for efficacy of antihistamines (H1 receptor antagonists), but there were significant concerns about risks associated with the use of these agents. While the advantages of these drugs are their low cost and easy availability, the disadvantages are inconsistent efficacy, rapid development of tolerance to sedative effects, potential for residual effects, no well-defined effective dose and poorly defined half-life. The adverse effects of antihistamines can include dry mouth, blurred vision, urinary retention, constipation, risk of increased intraocular pressure in individuals with narrow angle glaucoma, residual daytime sedation, and anticholinergic effects which may lead to diminished cognitive function and delirium (which is of particular concern in the elderly) (Richardson et al. 2002).

Although the sedating antidepressants, such as trazodone or doxepin, are widely used off-label for the treatment of chronic insomnia, the NIH (National Institutes of Health 2005) concluded that all antidepressants have potentially significant adverse effects, raising concerns about the risk-benefit ratio. Trazodone, for example, has a 6.4-hr half-life in adults, and an 11.6-hr half-life in elderly. It is perceived to be safe, has generic availability, unscheduled status and lack of restrictions on prescription drug...
duration. However, there are very few controlled studies of trazodone, with most trials usually consisting of less than 30 patients, of short duration (≤ 3 weeks), conducted in patients with comorbid depression or serotonin reuptake inhibitor (SSRI)-induced insomnia, and rely on solely on subjective measurements (Mendelson 2005). In a 2-week study comparing trazodone 50 mg to zolpidem 10 mg and placebo in 306 insomnia patients, both trazodone and zolpidem significantly improved subjective sleep latency, sleep duration, number of awakenings, and wake time after sleep onset (WASO) during the first week (although sleep latency was significantly shorter with zolpidem). By the second week, however, there was no difference between trazodone and placebo (Walsh et al. 1998). Adverse effects of trazodone include drowsiness, dizziness, dry mouth, priapism, orthostatic hypotension and other cardiovascular events (Mendelson 2005). While sedating anti-depressants may be potentially advantageous for patients experiencing chronic insomnia with depression, there are little data to suggest efficacy in nondepressed patients with insomnia.

Use of other off-label medication, such as antipsychotics and anti-convulsants was also discouraged as studies demonstrating the usefulness of these medications for the treatment of insomnia are lacking (National Institutes of Health 2005). The panel also concluded that there were greater risks than benefits with these medications. The use of antipsychotic medications also raises the risk of tardive dyskinesia, weight gain and development of type II diabetes mellitus.

The only U.S. Food and Drug Administration (FDA) approved medications for insomnia are the benzodiazepine receptor agonists (the older benzodiazepines and the newer nonbenzodiazepines) and one MT receptor agonist (see Tables 79–7 and 79–8). The older benzodiazepines are non-selective agonists of BZD benzodiazepine receptors whose advantages are decreased sleep latency and increased total sleep time, but whose risks include daytime sedation, cognitive impairment, motor incoordination, dependence and abuse, tolerance development and rebound insomnia after withdrawal (Mendelson et al. 2004).

The newer nonbenzodiazepines, eszopiclone, zaleplon, and zolpidem preferentially bind to the benzodiazepine receptor, enhancing the effect of gamma-Aminobutyric acid (GABA) alpha subunits 1–3 on the ventrolateral preoptic nucleus, promoting sleep (Dawson et al. 2005). The newer, nonbenzodiazepine receptor agonists have fewer side effects as they act on selected alpha sub-units of the GABA receptors.

Ramelteon is a selective agonist of MT (MT1 and MT2) receptors, and appears to work exclusively through effects on the SCN activity (Dubocovich et al. 2003). It is believed that the activity of ramelteon is the result of inhibition of alertness in the SCN (MT1) and entrainment of the sleep/wake rhythm (MT2). Ramelteon is the only FDA-approved hypnotic that is not a controlled substance due to its lack of significant or clinically relevant residual effects such as abuse potential, dependence, development of tolerance, withdrawal syndrome/rebound insomnia in clinical trials (McGechan and Wellington 2005).

The NIH, in reviewing the benzodiazepine receptor agonists, concluded that short, intermediate and long-acting benzodiazepines are all efficacious, but that short-acting nonbenzodiazepine hypnotics are effective in initiating sleep and/or maintaining sleep and have superior safety/adverse event profile to older agents (National Institutes of Health 2005). It is important to note that at the time of the NIH conference held in June 2005, ramelteon had not yet been FDA-approved and therefore was not considered as part of the conference or its conclusions.

Patients should be educated about the anticipated benefits and limitations of sleeping pills, side effects, and appropriate use, and should be followed up by office visits or phone calls regularly if prescriptions are renewed. Treatment of these patients should focus on the lowest possible effective dose for the treatment of insomnia.

### General Approaches to the Clinical Management of Sleep Disorders in Psychiatric Patients

The sleep complaint in the patient with an apparent psychiatric disorder deserves the same careful diagnostic and therapeutic attention that it does in any patient. Just because a patient is depressed does not mean that the complaint of insomnia or hypersomnia can be explained away as a symptom of depression. Too many patients with depression have been found to have a breathing-related sleep disorder; too many patients with panic disorder to have insomnia secondary to caffeine. Chronic sleep complaints are multidetermined and multifaceted, even in many psychiatric patients. Differential diagnosis remains the first obligation of the psychiatrist before definitive treatment, which should be aimed at the underlying cause or causes.
Nonspecific treatments, such as use of sleep hygiene principles, are often helpful for both the sleep complaints and the underlying psychiatric disorders. In particular, bipolar disorder patients and patients whose daily activities are poorly organized (like patients with chronic schizophrenia and patients with certain personality disorders) may benefit from fairly rigid sleep–wake and light–dark schedules to synchronize circadian rhythms and impose structure on their behavior. Physical exercise, meditation, relaxation methods, sleep restriction therapy, and cognitive psychotherapy may help patients manage anxiety, rumination, and conditioned psychophysiological insomnia that often cause sleeplessness at night and fatigue during the day. Partial or total sleep deprivation may be like “paradoxical intention” therapy in the treatment of major depressive disorder or premenstrual dysphoric disorder but should probably be avoided in bipolar depression.

**Hypersomnia**

The most recent version of the International Classification of Sleep Disorders (American Academy of Sleep Medicine 2005) devotes a section to Hypersomnia of Central Origin, differentiated from Sleep-Related Breathing Disorders, which are also likely causes of excessive sleepiness. Within the Hypersomnia category, three conditions are of particular interest and relevance to psychiatrist: Narcolepsy, and Idiopathic and Recurrent Hypersomnia.

**Narcolepsy**

**Definition and Diagnostic Features**

Narcolepsy is associated with a pentad of symptoms: (1) EDS, characterized by irresistible “attacks” of sleep in inappropriate situations such as driving a car, talking to a supervisor, or social events, (2) cataplexy, a sudden bilateral loss of muscle tone, usually lasting seconds to minutes, generally precipitated by strong emotions such as laughter, anger, or surprise, (3) poor or disturbed nocturnal sleep, (4) hypnagogic hallucinations, varied dreams at sleep onset, and (5) sleep paralysis, a brief period of paralysis associated with the transitions into, and out of, sleep.

Narcolepsy is associated with significant social and financial impairment for affected individuals and their families. For example, automobile accidents may result from either sleepiness or cataplexy. Most states prohibit narcoleptic patients from driving, at least as long as they are symptomatic.

**Epidemiology**

Narcolepsy is not a rare disease. The prevalence rate of 0.03–0.16% approximates that of multiple sclerosis.

**Course**

The disorder is lifelong. The first symptom is usually excessive sleepiness, typically developing during the late teens and early twenties. The full syndrome of cataplexy and other symptoms may be seen in association with the initial complaints of excessive sleepiness, but more often presents at a later date, typically within several years but at time delayed as long as 20 years. Once established, the disorder may progress to some degree with regard to development of additional symptoms (i.e., cataplexy and/or other REM-intrusion symptoms), but patients typically do not experience a progression in the severity of their hypersomnia complaints.

**Differential Diagnosis**

Observers may mistake classic sleepiness in its mild form as withdrawal, poor motivation, negativism, and hostility. The hypnagogic imagery and sleep paralysis symptoms, alone and in combination, may resemble bizarre psychiatric illness. Like many medical disorders, narcolepsy presents a wide range of severity, from mild to cases so severe that employment is functionally impossible. Partial remissions and exacerbations occur. Sleep paralysis and hypnagogic imagery may be seen without cataplexy; cataplexy may present in isolation without other REM-associated phenomena. The presence of REM sleep onset at night or during daytime naps, an important sleep laboratory parameter, remains the most valid and reliable method available for diagnosing narcolepsy. Because of the seriousness of the disorder and likelihood that amphetamine or other stimulants will be used to treat the patient at some time, it is important that the diagnosis of narcolepsy be objectively verified as soon as possible. Furthermore, stimulant abusers have been known to feign symptoms of narcolepsy to obtain prescriptions.

**Etiology and Pathophysiology**

Narcolepsy is now understood as a physiological disturbance of REM sleep regulation, whose etiology is determined by both hereditary and autoimmune components (Lin et al. 1999, Nishino et al. 2000, Chemelli et al. 2005). It is also seen in dogs and other mammals. Genetic markers in humans (Nishino et al. 2000, Mignot et al. 1991, 1993) and basic neurochemical and neurophysiological studies in...
canine narcolepsy (Lin et al. 1999, Mignot et al. 1993, Siegel et al. 1992) may clarify the basic pathophysiological process of human narcolepsy.

Narcoleptic patients often enter REM sleep right after sleep onset (“sleep-onset REM periods”), reflecting an abnormally short or even nonexistent first NREM sleep period (Figure 79–6). Several of the core symptoms of narcolepsy can be understood as abnormal physiological representations of normal REM sleep. For example, cataplexy can be understood as an abrupt presentation during wakefulness of the paralysis normally seen in REM sleep. Cataplexy is usually triggered by an emotional stimulus. Sleep-onset REM periods may be subjectively appreciated as hypnagogic hallucinations, which may be accompanied by sleep paralysis. Dissociated REM sleep inhibition of the voluntary musculature may lead to complaints of cataplexy and sleep paralysis.

A strong association between narcolepsy and the human leukocyte antigen HLA-DR2 phenotype has been demonstrated (Rosenthal et al. 1991). Studies to date suggest that between 90 and 100% of Asian and white narcoleptics have the HLA-DR2 and DQwl phenotype, versus 20–40% of nonnarcoleptic control subjects. The frequent occurrence of this trait in “normal” populations limits the utility of this test for diagnostic purposes.

In recent years, a potential biochemical abnormality has been identified in both canine and human narcolepsy. Narcoleptic dogs appear to have a nonfunctional type 2 orexin receptor (OX2R) for orexin (hypocretin), a peptide neurotransmitter that has also been associated with feeding and energy metabolism. “Knockout” mice, which no longer make this peptide, appear to have a narcoleptic-like syndrome. Levels of orexin/hypocretin have been reported to be low in both autopsied brains and spinal fluid in human narcoleptics (Lin et al. 1999, Nishino et al. 2000, Chemelli et al. 2005).

Treatment

**Treatment Goals**

The major goals of treatment of narcolepsy include: (a) to improve quality of life, (b) to reduce EDS, and (c) to prevent cataplectic attacks.

**Pharmacological Treatment**

The major wake-promoting medications are: modafinil, various formulations of amphetamines, and methylphenidate. Modafinil is preferred on grounds of efficacy, safety, availability, and low risk of abuse and diversion. SSRIs such as fluoxetine and citalopram and tricyclic antidepressants such as protriptyline and clomipramine have been used to treat cataplexy, sleep paralysis, and hypnagogic hallucinations. Relatively little research data exist supporting the use of these agents, whose therapeutic effects are presumed to be related to their REM-suppressant effects, which may partially or completely block the appearance of REM-related symptoms (i.e., cataplexy, sleep paralysis, and hypnagogic hallucinations).

Another new drug, sodium oxybate (Xyrem), has been approved by the FDA for treatment of narcolepsy. Xyrem is another name for Gamma Hydroxybutyrate (GHB), a potent CNS sedative which has been demonstrated to be effective for treatment of cataplexy and symptoms of sleepiness in patients with narcolepsy. (Littner et al. 2001). GHB has been widely abused as an intoxicant and has become notorious as a “date-rape” drug. As a consequence of its abuse potential, access to it is tightly-controlled and it is available only through a single central pharmacy.

Xyrem is taken as an oral solution, mixed with water. Xyrem is usually taken in two divided doses, the first administered at bedtime and the second 2.5–4 hr later. Daily dosages typically range from 5–9 g. Side effects are usually minor and related to the sedative properties of the compound, but can include headache, dizziness, weakness, enuresis, and encopresis.

**Primary Hypersomnia**

**Idiopathic and Recurrent Hypersomnia**

**Diagnosis**

**Definition and Diagnostic Features**

Idiopathic hypersomnia, also known as primary hypersomnia, has often been considered to be a “wastebasket” diagnosis, a condition diagnosed when excessive sleepiness was present but no other diagnosis (i.e., narcolepsy) would explain symptomatic complaints. Indeed, in the past this disorder was called “NREM Narcolepsy.” However, specific diagnostic criteria for this condition are included in DSM-IV-TR, defining a disorder characterized by clinically significant excessive sleepiness of at least 1 month’s duration, with significant distress or impairment. The hypersomnia is not caused by another
primary sleep disorder, a psychiatric disorder, a medical disorder, or a substance.

Patients with primary hypersomnia usually present with complaints of long and nonrestorative nocturnal sleep, difficulty awakening (“sleep drunkeness”), and daytime sleepiness and intellectual dysfunction; do not experience the accessory symptoms of narcolepsy such as cataplexy, sleep paralysis, and hypnagogic hallucinations; and often report frequent headaches and Raynaud’s phenomena. Onset usually occurs before 25 years of age, and the condition is typically chronic once it has presented.

**Assessment.** A formal diagnosis requires polysomnographic confirmation of hypersomnia; based on objective levels of sleepiness in a formal MSLT, performed in a sleep laboratory setting following a night of nocturnal PSG that excludes the presence of other causes for excessive sleepiness (i.e., Sleep Apnea, Sleep Deprivation, PLMS, etc). Limited data obtained from normal subjects suggests that healthy normal individuals will demonstrate a MSLT sleep latency of about 10 min. It is to be expected that patients with narcolepsy will usually have a mean MSLT sleep latency of 8 min or less. At least one Sleep Onset REM Period (SOREMP) is expected in the patient with narcolepsy, but when strong clinical findings are present (i.e., observed cataplexy), the diagnosis may be made in the absence of a SOREM. Subjective complaints of excessive sleepiness are not adequate. A family history of excessive sleepiness may be present, but is not needed to make the diagnosis.

Aside from associated medical and psychiatric disorders, the frequency and importance of hypersomnia and daytime sleepiness in otherwise healthy individuals have been increasingly recognized. Sleepiness, for example, as a result of sleep deprivation, disrupted sleep, or circadian dyssynchronization, probably plays a major role in mistakes and accidents in sleepy drivers, interns and medical staff, and industrial workers. Psychiatrists have an obligation to recognize and advise their patients about the dangers inherent in acute or chronic sleepiness.

**Epidemiology.** This is an uncommon disorder, representing 5–10% of patients presenting to sleep disorders centers for evaluation of hypersomnia. It is extremely rare in the general population, with a prevalence estimated to be as low as 20–50 per million.

Although usually seen as a persistent complaint, the DSM-IV-TR category for Primary Hypersomnia includes recurrent forms, conditions that are categorized separately in the International Classification of Sleep Disorders (American Academy of Sleep Medicine 2005). Patients with recurrent forms of hypersomnia present with well-defined periods of excessive sleepiness of at least 3 days’ duration, occurring several times a year for at least 2 years. Among the recurrent or intermittent hypersomnia disorders are Kleine–Levin syndrome, usually seen in adolescent boys, and menstrual cycle-associated hypersomnia syndrome. In addition to hypersomnia (up to 18 hr per day), patients with Kleine–Levin syndrome often demonstrate aggressive or inappropriate sexuality, compulsive overeating, and other bizarre behaviors. The rare nature of this syndrome and its unusual behaviors may be mistaken for psychosis, malingering, or a personality disorder.

---

**DSM-IV-TR Criteria**

### Primary Hypersomnia

**A.** The predominant complaint is excessive sleepiness for at least 1 month (or less if recurrent) as evidenced by either prolonged sleep episodes or daytime sleep episodes that occur almost daily.

**B.** The excessive sleepiness causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**C.** The excessive sleepiness is not better accounted for by insomnia and does not occur exclusively during the course of another sleep disorder (e.g., narcolepsy, breathing-related sleep disorder, circadian rhythm sleep disorder, or a parasomnia) and cannot be accounted for by an inadequate amount of sleep.

**D.** The disturbance does not occur exclusively during the course of another mental disorder.

**E.** The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

**Specify if:**

**Recurrent:** if there are periods of excessive sleepiness that last at least 3 days occurring several times a year for at least 2 years

---

**Differential Diagnosis.** This diagnosis is at times used “casually” to describe patients with sleepiness complaints without narcolepsy or sleep apnea.

**Etiology and Pathophysiology.** Little is known about the causes of this rare disorder. It has been observed in families with histories of narcolepsy, suggesting that (in some cases it may be a “forme-fruste” or variant of narcolepsy.

**Treatment**

Clinical management is controversial, owing to the lack of controlled studies. As in narcolepsy, stimulants such as amphetamines or methylphenidate may be used, but use of these compounds is always complicated by risks of abuse and diversion, and by side effects including anxiety, agitation, elevation of blood pressure, and cardiac arrhythmias. Modafinil may also be used, although this use would be “off-label” as this is not an FDA-approved use for this compound.

However, some patients are intolerant of stimulants or report no significant therapeutic effects. For patients intolerant of, or insensitive to, stimulants, some success has been reported with the use of antidepressants, both of the monoamine oxidase inhibitors (MAOI) and the selective SSRI classes. Methysergide, a serotonin receptor antagonist, has been reported to be effective in some treatment-resistant
cases, but must be used with caution in view of the risk that retroperitoneal fibrosis may develop in association with persistent, uninterrupted use.

**Breathing Related Sleep Disturbances (BRSD)**

The essential feature of BRSD is sleep disruption resulting from sleep apnea or alveolar hypoventilation, leading to complaints of insomnia or, more commonly, excessive sleepiness. The disorder is not accounted for by other medical or psychiatric disorders or by medications or other substances.

**Diagnosis**

**Definition and Diagnostic Features**

The major diagnostic criterion for sleep apnea is cessation of breathing lasting at least 10 s. Hypopneas (50% decrease in respiratory effort) may also produce arousal or hypoxia even when complete apneas do not occur. An apnea-hypopnea index (AHI; number of apneas and hypopneas per hour of sleep; also called respiratory disturbance index or RDI) of 5 or more (Figure 79–7) is needed for a diagnosis. Most apneic episodes are terminated by transient arousals. Each time respiration ceases, the individual must awaken to start breathing again. Once the person goes back to sleep, breathing stops again. This pattern continues throughout the night. Clinically, however, it is not unusual to see patients who stop breathing for 60–120 s with each event and experience hundreds of events per night. Many individuals with BRSD cannot sleep and breathe at the same time and therefore spend most of the night not breathing and not sleeping.

Obstructive sleep apnea is characterized by repetitive episodes of upper airway obstruction that occur during sleep, resulting in numerous interruptions of sleep continuity, hypoxemia, hypercapnia, bradytachycardia, and pulmonary and systemic hypertension. It may be associated with snoring, morning headaches, dry mouth on awakening, excessive movements during the night, falling out of bed, enuresis, cognitive decline and personality changes, and complaints of either insomnia or, more frequently, hypersomnia and EDS. The typical patient with clinical sleep apnea is a middle-aged man who is overweight or who has anatomical conditions narrowing his upper airway.

There are three types of apnea. The first is obstructive sleep apnea, which involves the collapse of the pharyngeal airway during inspiration, with partial or complete blockage of airflow. The person still attempts to breathe and one can observe the diaphragm moving, but the airway is blocked and therefore there is no air exchange. It can be caused by bagginess or by excessive pharyngeal mucosa and a large uvula, fatty infiltration at the base of the tongue, or by collapse of the pharyngeal walls. The resulting decreased air passage...
compromises alveolar ventilation and causes blood-oxygen desaturation and strenuous attempts at inspiration through the narrowed airway, all of which lighten and disrupt sleep. Hypcapnia, which may occur in association with long-standing sleep apnea obstructive sleep apnea or chronic obstructive lung disease, may blunt ventilatory drive on chemical grounds without any obstruction of inspiratory efforts.

The second type is central sleep apnea, which results from failure of the respiratory neurons to activate the phrenic and intercostal motor neurons that mediate respiratory movements. There is no attempt to breathe, and although the airway is not collapsed, there is no respiration. This type of apnea is more commonly associated with heart disease.

The third type is mixed sleep apnea, which is a combination, generally beginning with a central component and ending with an obstructive component.

During apneas and hypopneas, the blood-oxygen level often drops to precarious levels. In addition, one often sees cardiac arrhythmias and nocturnal hypertension in association with the respiratory disturbances. The cardiac arrhythmias include bradycardia during the events and tachycardia after the end of the events. It is not unusual to see premature ventricular contractions, trigeminy and bigeminy, asystole, second-degree atrioventricular block, atrial tachycardia, sinus bradycardia, and ventricular tachycardia. However, the electrocardiogram taken during the waking state might be normal. It is only during the respiratory events during sleep that the abnormalities appear. Some of these rhythms may be lethal, and Caples et al. (Caples et al. 2007) has speculated that cardiac rhythm abnormalities associated with apnea may explain increased death rates in morning hours seen in sleep apnea patients. Health and longevity effects of apnea are usually assumed to relate primarily to increased risk of hypertension, heart disease and stroke.

The most common symptoms of BRSD include EDS and snoring. The EDS probably results from sleep fragmentation caused by the frequent nocturnal arousals occurring at the end of the apneas, and possibly from hypoxemia. The EDS is associated with lethargy, poor concentration, decreased motivation and performance, and inappropriate and inadvertent attacks of sleep. Sometimes the patients do not realize they have fallen asleep until they awaken.

The second complaint is loud snoring, sometimes noisy enough to be heard throughout or even outside the house. Often the bed-partner has complained for years about the snoring and has threatened to sleep elsewhere if she has not moved out already. Bed partners describe a characteristic pattern of loud snoring interrupted by periods of silence, which are then terminated by snorting sounds. Snoring results from a partial narrowing of the airway caused by multiple factors, such as inadequate muscle tone, large tonsils and adenoids, long soft palate, flaccid tissue, acrogaly, hypothyroidism, or congenital narrowing of the oral pharynx. Because the prevalence of snoring increases with age, especially in women, and because snoring can have serious medical consequences, the psychiatrist must give serious attention to complaints of loud snoring. Snoring is not always a symptom of BRSD. Approximately 25% of men and 15% of women are habitual snorers.

Patients with BRSD are frequently overweight. In some patients, a weight gain of 20 to 30 lb might bring on episodes of BRSD. The same fatty tissue seen on the outside is also present on the inside of the throat, making the airway even more narrow. Because obstructive sleep apnea is always caused by the collapse of the airway, in patients of normal weight, anatomical abnormalities (such as large tonsils, long uvula) must be considered.

Other symptoms of BRSD include unexplained morning headaches, nocturnal confusion, automatic behavior (i.e., behavior that is performed without conscious knowledge and that does not appear to be under conscious control) or night sweats. The severity of BRSD will depend on the severity of the cardiac arrhythmias, hypertension, EDS, respiratory disturbance index, amount of sleep fragmentation, and amount of oxygen desaturation.

Epidemiology: The lifetime prevalence of BRSD in adults has been estimated to be 9% in men and 4% in women (Young et al. 1993). The prevalence does increase with age, particularly in postmenopausal women. The prevalence in the elderly has been estimated to be 28% in men and 19% in women (Ancoli-Israel et al. 1991b).

Comorbidity Patterns: BRSD, especially central sleep apnea, is commonly seen in patients with congestive heart failure. Cor pulmonale may also be a consequence of long-standing BRSD and is seen in both sleep apnea syndrome and primary hypoventilation. Patients may present with unexplained respiratory failure, polycythemia, right ventricular failure, and nocturnal hypertension. About 50% of patients with BRSD have hypertension, and about one-third of all hypertensive patients have BRSD. The large cross-sectional Sleep Heart Health Study found that the increased risk for hypertension for those with severe sleep apnea, when compared to those with no sleep apnea, was significant at 1.37. In addition, associations of hypertension with measures of systolic and diastolic blood pressure (SDB) were seen in men and women, older and younger ages, all ethnic groups, and among normal-weight and overweight individuals (Nieto et al. 2000). It has also been shown that there is a dose–response association between SDB at baseline and

---

**DSM-IV-TR Criteria**

**Breathing-Related Sleep Disorder**

A. Sleep disruption, leading to excessive sleepiness or insomnia that is judged to be due to a sleep-related breathing condition (e.g., obstructive or central sleep apnea syndrome or central alveolar hypoventilation syndrome).

B. The disturbance is not better accounted for by another mental disorder and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or another general medical condition (other than a breathing-related disorder).

Coding note: Also code sleep-related breathing disorder on Axis III.

---

Clinical Symptoms of BRSDs

Hypertension 4 years later suggesting that SDB may be a risk factor for hypertension and consequent cardiovascular morbidity (Peppard et al.).

Course: Mild-to-moderate sleep-related breathing disturbances increase with age, even in elderly subjects without major complaints about their sleep. The frequency is higher in men than in women, at least until the age of menopause, after which the rate in women increases and may approach that of men. In general, the severity of apnea in these older persons is mild compared with what is seen in patients with clinical sleep apnea. However, older men and women with mild apnea have been reported to fall asleep at inappropriate times significantly more often than older persons without apnea. Furthermore, the frequency of sleep apnea and other BRSDs is higher in individuals with hypertension, congestive heart failure, obesity, dementia, and other medical conditions. Research studies have demonstrated that treatment with nasal continuous positive airway pressure (CPAP) can reduce blood pressure in patients with hypertension, prevent recurrence of atrial fibrillation, and even reverse atherosclerotic changes in patients with coronary artery disease (McNicholas 2007, Sanner et al. 2002).

The clinical significance of relatively mild “subclinical” sleep apneas is not fully understood yet. Psychiatrists should be aware, however, that such disturbances might be associated with either insomnia or EDS. Furthermore, for some patients with sleep apnea, administration of hypnotics, alcohol, or other sedating medications is relatively contraindicated. The risk is not yet known, but reports indicate that the older benzodiazepines (but not the newer nonbenzodiazepines) as well as alcohol may increase the severity of mild sleep apnea. Therefore, psychiatrists should inquire about snoring, gasping, and other signs and symptoms of sleep apnea before administering a sleeping pill. If patients have excessive sleepiness or morning hangover effects while taking benzodiazepines, major tranquillizers, or other sedating medications, the psychiatrist should consider the possibility of an iatrogenic BRSD due to medications.

**Differential Diagnosis**

The diagnosis of BRSD must be differentiated from other disorders of excessive sleepiness such as narcolepsy (Table 79–10). Patients with BRSD will not have cata-

**Circadian Rhythm Sleep Disorder (Sleep–Wake Schedule Disorders)**

**Diagnosis**

Definition and Diagnostic Features: Circadian rhythm disturbances result from a mismatch between the internal or endogenous circadian sleep–wake system and the external or exogenous demands on the sleep–wake system. Thus, the individual’s tendency to sleep–wakefulness does not match that of her or his social circumstances or of the light–dark cycle. Although some individuals do not find this mismatch to be a problem, for others the circadian rhythm disturbance interferes with the ability to function properly at times when alertness or sleepiness is desired or required. For those individuals, insomnia, hypersomnia, sleepiness, and fatigue result in significant discomfort and impairment. The more common circadian rhythm disturbances include delayed and advanced sleep phase, shift work and jet lag.

**Delayed and Advanced Sleep Phase Disorders**

Delayed sleep phase refers to a delay in the circadian rhythm in the sleep–wake cycle. These individuals are generally not sleepy until several hours after “normal” bedtime (i.e., 2–3 AM). If allowed to sleep undisturbed, they will sleep for 7 or 8 hr, which means they awaken at 10–11 AM. People with delayed sleep phase are considered extreme “owls.” They may or may not complain of sleep-onset insomnia. They usually enjoy their alertness in the evening and night and have little desire to sleep beginning at 10 PM or midnight. Their problem is trying to wake up at normal times (i.e., 6–7 AM). In essence, their rhythm is shifted to a later clock time relative to conventional rest–activity patterns.

*Specify type:*

- **Delayed sleep phase type:** A persistent pattern of late sleep onset and late awakening times, with an inability to fall asleep and awaken at a desired earlier time.
- **Jet lag type:** Sleepiness and alertness that occur at an inappropriate time of day relative to local time, occurring after repeated travel across more than one time zone.
- **Shift work type:** Insomnia during the major sleep period or excessive sleepiness during the major awake period associated with night shift work or frequently changing shift work.
- **Unspecified type**

Individuals with delayed sleep phase often choose careers that allow them to set their own schedules, such as freelance writers. Delayed sleep phase occurs commonly in late adolescence and young adulthood, such as in college students. As many of these individuals age, however, their endogenous sleep–wake rhythm advances and they eventually are able to conform themselves to a normal rest period at night.

As people age, the endogenous oscillator continues to advance resulting in an advanced sleep phase. In this condition, individuals become sleepy earlier in the evening (e.g., 7–8 PM). They will also sleep for 7 to 8 hr, but that means they awaken at 2 to 3 AM. These individuals are “larks,” being most alert in the morning. They complain of sleep maintenance insomnia, that is, they cannot stay asleep all night long.

**Assessment**

The diagnosis of circadian rhythm disturbances is based on a careful review of the history and circadian patterns of sleep–wakefulness, napping, alertness, and behavior. According to DSM-IV-TR criteria, the diagnosis of circadian rhythm sleep disorder requires significant social or occupational impairment or marked distress related to the sleep disturbance. It is often useful for patients with chronic complaints to keep a sleep–wake diary covering the entire 24-hr day each day for several weeks. If possible, an ambulatory device that measures rest–activity, such as a wrist actigraph, might supplement the sleep–wake diary. Wrist actigraphs record acceleration of the wrist at frequent intervals, such as every minute, and save it for later display. Because the wrist is mostly at rest during sleep, the record of wrist rest–activity provides a fairly accurate estimate of the timing and duration of sleep–wakefulness. In addition, some commercial wrist activity devices have a built-in photometer, which provides a record of ambient light–darkness against which the rest–activity pattern can be compared.

**Epidemiology**

Although formal epidemiologic data is not available, clinical experience suggests that delayed sleep phase is more common in adolescence, while advanced sleep phase is more prevalent in the elderly.

**Etiology and Pathophysiology**

The etiology of extreme “night owls” and “larks” is probably multifaceted but, in at least some cases, appears to reflect genetic factors. Jones et al. (1999) described a family in which extreme phase advance (bedtime about 7 PM) appeared to be consistent with an autosomal dominant trait. One member of the family was studied in a temporal isolation facility; as predicted, her endogenous sleep–wake cycle averaged less than 24 hr, clearly different from most subjects who average about 24.2–24.5 hr. Members of this family appear to have a mutation of one of the “clock genes.” Mignot et al. (1998) have also identified a single nucleotide polymorphism of the human CLOCK gene in people self-described as “night owls.” In addition, Ancoli-Israel and colleagues (Ancoli-Israel et al. 2001) identified a pedigree of one family with phase delay.

**Treatment**

**Treatment Goals**

Clinical management includes strategies to shift the phase of the endogenous circadian clock in the appropriate direction.

**Somatic Treatments**

Exposure to bright light in the morning advances the delayed sleep phase; that is, individuals will become sleepy earlier in the evening. On the other hand, administration of bright light in the evening acts to delay the circadian rhythm; that is, individuals will get sleepy later in the evening. For some individuals, spending more time outdoors in bright sunlight may be sufficient to treat the sleep phase. For example, individuals with delayed sleep phase should be encouraged to remove blinds and curtains from their windows, which would allow the sunlight to pour into their bedrooms in the morning when they should arise. When natural sunlight cannot be used to shift the circadian rhythm, light boxes can be
Shift Work Sleep Disorder

Diagnosis

Definition and Diagnostic Features

Shift work problems occur when the circadian sleep–wake rhythm is in conflict with the rest–activity cycle imposed by the externally determined work schedule. Different patterns include rotating schedules and more or less permanent evening and night schedules. Rotating schedules, particularly rapidly shifting schedules, are difficult because constant readjustment of the endogenous circadian oscillator to the imposed sleep–wake cycle is necessary. In both rotating and evening/night shift work schedules, further difficulties are encountered because the worker is usually expected to readjust to a normal sleep–wake cycle on weekends and holidays. Even if the worker can adjust his or her circadian system to the work schedule, he or she is then out of synchrony with the rhythm of family and friends during off-duty hours. These individuals, therefore, are constantly sleep deprived and constantly sleepy. They endure impaired performance and increased risk of accidents, somatic complaints, and poor morale; hypnotics, stimulants, and alcohol are often used excessively in relationship to unusual or shifting work schedules.

A specific disorder associated with shift work, Shift Work Sleep Disorder, has been defined and is included in the most recent International Classification of Sleep Disorders (American Academy of Sleep Medicine 2005). This condition is identified as Circadian Rhythm, Shift Work Type, in DSM-IV-TR. Based on research data showing symptomatic improvements in treated shift workers (Czeisler et al. 2005), the FDA has approved a specific pharmacological treatment (modafinil 200 mg, 1 hr before the start of shift work) for this disorder.

Epidemiology

Nearly a quarter of all American employees have jobs that require them to work outside the conventional 8 AM –5 PM schedule.

Treatment

No totally satisfactory methods currently exist for managing shift work problems. Because people vary in their ability to adjust to these schedules, self-selection or survival of the fittest may be involved for those who cannot find other employment or work schedules. Older individuals appear to be less flexible than younger persons in adjusting to shift work. Some experiments suggest that the principles of chronobiology may be useful in reducing the human costs of shift work. For example, because the endogenous pacemaker has a cycle length (tau) longer than 24 hr, rotating shift workers do better when their schedules move in a clockwise direction (i.e., morning to evening to night) rather than in the other direction. Appropriate exposure to bright lights and darkness may push the circadian pacemaker in the correct direction and help stabilize its phase position, especially in association with the use of dark glasses outside and blackout curtains at home to maintain darkness at the appropriate times for promotion of sleep and shifting of the circadian pacemaker. Naps may also be useful in reducing sleep loss. Modest amounts of coffee may maintain alertness early in the shift but should be avoided near the end of the shift.

The FDA has approved the use of modafinil for the treatment of shift work sleep disorder. Recent research has demonstrated that subjects in performing shift work receiving modafinil, compared to placebo, demonstrated improved alertness, improved clinician ratings of well-being, improved quality of life and improved performance and alertness (Czeisler et al. 2005). Stimulants may also improve levels of alertness and performance of shift workers, but pose greater risks of side effects diversion and abuse, and not approved treatments for this disorder.

Jet Lag

Diagnosis

Definition and Diagnostic Features

Jet lag occurs when individuals travel across several time zones. Traveling east advances the sleep–wake cycle and is typically more difficult than traveling west (which delays the cycle). Jet lag may be associated with difficulty initiating or maintaining sleep or with daytime sleepiness, impaired performance, and gastrointestinal disturbance after rapid transmeridian flights. Individuals older than 50 years appear to be more vulnerable to jet lag than are younger persons.

Treatment

Considerable research and theorizing are under way to better prevent and manage the problems associated with jet lag. Some efforts before departure may be useful to prevent or ameliorate these problems. For persons who plan to readjust their circadian clock to the new location, it may be possible to move the sleep–wake and light–dark schedules appropriately before departure. In addition, good sleep hygiene principles should be respected before, during, and after the trip. For example, many people are sleep deprived or in alcohol withdrawal when they step on the plane because of last-minute preparations or farewell parties. Whereas adequate fluid intake on the plane is necessary to avoid dehydration, alcohol consumption should be avoided or minimized because it causes diuresis and may disrupt sleep maintenance.

On arriving at the destination, it may be preferable to try to maintain a schedule coinciding with actual home time if the trip is going to be short. For example, the individual should try to sleep at times that correspond to the usual bedtime or with the normal mid-afternoon dip in alertness. If, on the other hand, the trip will be longer and it is desirable to synchronize the biological clock with local time, exposure to appropriate schedules of bright light and darkness may be helpful, at least theoretically.

Specific algorithms that may be helpful in resetting circadian rhythms are extremely complex, relating to the time hour of departure and arrival, times of sunrise and sunset, and the number of hours and direction that rhythms have been shifted (i.e., has the traveler advanced his or her clock by 8 hr, flying from San Diego to Paris, or delayed it by
15 hr, flying from New York City to Beijing). Some sleep hygiene suggestions are likely to be of benefit for all jet-lagged travelers. Obtaining light during the daylight hours at one’s destination will help the brain recognize and adapt to local time; obtaining light exposure when one is sleepy during daylight hours will promote alertness and may help to speed entrainment to local time.

Although brief naps (i.e., of up to 20 min) may be restorative, longer naps (which may occur in response to timing of periods of sleep which would be occurring in one’s home time zone) may interfere with adaptation to local time. Caffeine, if tolerated well and not contraindicated on medical grounds, will promote alertness and may help to minimize drowsy episodes during the “work” day at a time-shifted destination. Alcohol use, although helpful in promoting sleep and (perhaps) socially appropriate at a travel destination, will disrupt and fragment sleep in the hours after ingestion and should be avoided for the first few nights when jet lag is a problem.

In addition to synchronizing the clock with the new environment, sleep and rest should be promoted by good sleep hygiene principles, by avoidance of excessive caffeine and alcohol, and, when necessary, by administration of short-duration hypnotics. Because individual responses to sleeping pills vary considerably from person to person, it is often helpful to develop experience with specific compounds and doses before departure. Although use of MT to ameliorate effects of jet lag is often mentioned in suggestions for travelers, research data has not demonstrated clinical benefit. Preliminary studies have suggested that ramelteon may have circadian phase-shifting properties that might be of benefit; this is not yet an approved use for this medication.

**PLMS and Restless Legs Syndrome (RLS)**

**Diagnosis**

**Definition and Diagnostic Features**

PLMS is a disorder in which repetitive, brief, and stereotyped limb movements occur during sleep, often with a periodicity of about 20–40 s. Dorsiflexions of the big toe, ankle, knee, and sometimes the hip are involved (Table 79–11 and Figure 79–8). Most patients will demonstrate repetitive episodes of PLMS for periods of from a few minutes to an hour or more throughout the night. Rare patients will show continuous movements throughout the night.

A disturbance often comorbid with PLMS, RLS, is associated with disagreeable sensations in the lower legs, feet, or thighs that occur in a recumbent or resting position and cause an almost irresistible urge to move the legs (Walters et al. 1995). Patients with RLS describe the dyesthesias as aching, tingling, creeping, and crawling. Motor movement, such as walking, generally relieves the dyesthesias.

**Assessment**

**PLMS**

Questioning of the patient or bed partner often yields reports of restlessness, kicking, unusually cold or hot feet, disrupted and torn bedclothes, unrefreshing sleep, insomnia, or EDS. Patients may be unaware of these pathological leg movements or arousals, although their bed partners may be all too aware of the kicking, frequent movements, and restless sleep. If these disorders are strongly suspected, the patient should probably be referred to a sleep disorders laboratory for evaluation and an overnight polysomnogram with tibial EMGs. These disorders are often associated with transient arousals in the EEG recording. Since diagnosis is made when the periodic limb movement index (number of leg jerks per hour of sleep) is 5 or greater, accompanied by arousals, an overnight sleep recording is necessary in order to count the number of leg jerks. The jerks occur primarily in the legs but may also appear in less severe forms in the arms. The movements can be bilateral or unilateral and occur in Stage 1 and Stage 2 sleep. Patients often have reduced deep sleep because the jerks continually awaken them.

**RLS**

Since the restlessness is a subjective symptom, the diagnosis of RLS is made upon history, with a standardized,
validated questionnaire (Walters et al. 2003). Mild RLS is defined as symptoms that occur episodically and are associated with mild sleep disruption. Moderate RLS is defined as symptoms that occur less than twice a week and cause moderate sleep disruption and mild daytime dysfunction. Severe RLS is defined as symptoms that occur more than twice a week and cause severe sleep disruption and daytime dysfunction.

Whereas almost close to 70% of patients with RLS have PLMS, only about 20% of patients with PLMS have RLS. RLS may be frequent in patients with uremia and rheumatoid arthritis or in pregnant women. Ferritin levels should be measured in patients with RLS.

**Epidemiology**

Both PLMS and RLS usually occur in middle-aged people, but many patients report having had the same sensations as adolescents and even as children. In the older adult, the prevalence of PLMS has been estimated to be 45% (Ancoli-Israel et al. 1991a). The prevalence of RLS has been estimated to be between 2% and 15% of the general population (Berger and Kurth 2007).

**Comorbidity Patterns**

PLMS and RLS may develop in association with sleep disordered breathing and narcolepsy. In addition, they are sometimes seen comorbid with medical conditions (e.g., congestive heart failure, arthritis, leukemia, venous insufficiency, chronic lung disease), neurological disorders (e.g., Parkinson’s disease, low back pain, polio, peripheral neuropathy, chronic myelopathy), metabolic disorders (e.g., iron deficiency, anemia, uremia, hypothyroidism). Both conditions may be aggravated by tricyclic antidepressants, serotonin reuptake inhibitors, antihistamines, caffeine, and sleep deprivation.

**Etiology**

It has been suggested that both conditions are familial, perhaps due to an autosomal dominant gene. It has been shown that PLMS activity in family members is significantly higher for those diagnosed with RLS compared to those without RLS (Birinyi et al. 2006). This difference was greater for older than younger subjects. In a search for sequence variants contributing to RLS, a genomewide association study with two replication studies were performed, focusing patients with RLS and PLMS. A genomewide significant association with a common variant in an intron of BTBD9 on chromosome 6p21.2 was found (Stefansson et al. 2007).

**Treatment**

**Pharmacological Treatment**

The treatment of choice for both RLS and PLMS are the dopamine agonists (Table 79–12). To date, only ropinirole and pramipexole have been approved by the FDA for the treatment of RLS. RLS patients with low ferritin levels should also be treated with ferrous sulphate.

Opiates, such as oxycodone and propoxyphene, have also been demonstrated to be somewhat effective in the treatment of PLMS and RLS. Anticonvulsants, such as carbamazepine and gabapentin, clonazepam (a benzodiazepine anticonvulsant) are also effective in the treatment of PLMS and possibly for RLS.

**Parasomnias**

The parasomnias are a group of disorders characterized by disturbances of either physiological processes or behavior associated with sleep, but not necessarily causing disturbances of sleep or wakefulness.

**Nightmare Disorder**

**Diagnosis**

**Definition and Diagnostic Features**

The essential feature of this disorder is the repeated occurrence of frightening dreams that lead to full awakenings from sleep. The dreams or awakenings cause the individual significant distress or dysfunction. This is clearly distinguished from the phenomenon of lucid dreaming, awareness of dreams while asleep that the “lucid dreamer” can direct and control and for which there is clear recall on awakening. These dreams are usually experienced by the “lucid dreamer” as a pleasant and at times enlightening experience. It has been reported that subjects can develop a greater capacity for lucid dreaming by cognitive preparation and efforts to control dream content prior to sleep onset.

**Differential Diagnosis**

By DSM-IV-TR definition, the disorder is excluded if the nightmare occurs in the course of another mental or medical disorder or as a direct result of a medication or substance. Most nightmares occur during REM sleep; REM nightmares take place most often during the last half of the night when REM sleep is most common.

**Epidemiology**

Although adults may experience occasional nightmares, nightmares are seen essentially universally at some point in time in children between the ages of 3 and 6 years. The exact prevalence in children is unknown, but figures of between 30% and 90% for nightmares occurring “at least sometimes” have been reported in children (Partinen and Hublin 2005). Individuals with a history of nightmare will typically experience increased frequencies of nightmares when they are under stress, or in withdrawal from

Nightmare Disorder

A. Repeated awakenings from the major sleep period or naps with detailed recall of extended and extremely frightening dreams, usually involving threats to survival, security, or self-esteem. The awakenings generally occur during the second half of the sleep period.

B. On awakening from the frightening dreams, the person rapidly becomes oriented and alert (in contrast to the confusion and disorientation seen in sleep terror disorder and some forms of epilepsy).

C. The dream experience, or the sleep disturbance resulting from the awakening, causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The nightmares do not occur exclusively during the course of another mental disorder (e.g., a delirium, posttraumatic stress disorder) and are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Sleep Terror Disorder

Diagnosis

Definition and Diagnostic Features

This disorder is defined as repeated abrupt awakenings from sleep characterized by intense fear, panicky arousal (tachycardia, rapid breathing, and sweating), absence of detailed dream recall, amnesia for the episode, and relative unresponsiveness to attempts to comfort the person. Because sleep terrors occur primarily during delta sleep, they usually take place during the first third of the night. These episodes may cause distress or impairment, especially for caretakers who witness the event. Sleep terrors may also be called night terrors, pavor nocturnus, or incubus.

Sleep terrors do not appear to be associated with psychiatric illness in children. In adults, it is equally common in men and women, and may be associated with psychiatric disorders, such as posttraumatic stress disorder, generalized anxiety disorder, and borderline personality disorder. Stress and sleep deprivation may increase the occurrence of night terrors. An increased frequency of enuresis and somnambulism has been reported in the first-degree relatives of patients with night terrors.

Epidemiology

The prevalence of the disorder is estimated to be about 1–6% in children and less than 1% in adults. In children, it usually begins between the ages of 4 and 12 years and resolves spontaneously during adolescence. It is more common in boys than in girls. There is a strong genetic component, with high probability that one or both parents will have a history of sleep terrors, sleepwalking, or another parasomnia.

Course

In adults, sleep terrors usually begin between 20 and 30 years of age, with a chronic undulating course. The etiology of this disorder is unclear, but is presumed to relate to tendencies to spontaneous arousal from deep phases of nondreaming sleep.

Treatment

Sleep hygiene, such as obtaining adequate sleep and avoiding sleep deprivation, and reduction of stress are all important in reducing the probability of sleep terrors occurring. Maintaining a “safe” sleep environment (i.e., removing sharp or pointed objects that the sleeper could run into, having these individuals sleep in ground-floor bedrooms) may reduce the risk of harm. Nocturnal administration of benzodiazepines has been reported to be beneficial, perhaps because these agents. Although SSRIs do suppress REM activity, they also tend to lighten and fragment sleep. For this reason, sedating tricyclic and heterocyclic antidepressants (e.g., amitriptyline, doxepin, trazodone, etc.) may be used to try to reduce nightmare severity and promote sleep. Sedative hypnotic/anxiolytic agents do not suppress REM, but may prevent arousals in sleep caused by “anxious dreaming”/nightmares, and may reduce anxiety levels overall, reducing the probability that a nightmare will occur.
Whereas about 10−30% of children have at least one sleep-walking episode, only about 1−5% have repeated episodes. The prevalence in adults is unknown.

**Course**

The disorder most commonly begins between the ages of 4 and 8 years and usually resolves spontaneously during adolescence.

**Etiology**

Genetic factors may be involved, because sleepwalkers are reported to have a higher than expected frequency of first-degree relatives with either sleepwalking or sleep terrors. Sleepwalking may be precipitated in affected patients by gently sitting them up during sleep, by fever, or by sleep deprivation. Adult onset of sleepwalking should prompt the search for possible medical, neurological, psychiatric, pharmacological, or other underlying causes such as nocturnal epilepsy.

**Treatment**

No treatment for sleepwalking is established, but some patients respond to administration of benzodiazepines or sedating antidepressants at bedtime. The major concern should be the safety of the sleepwalker, who may injure herself or himself or someone else during an episode.
REM Behavior Disorder

Diagnosis

Definition and Diagnostic Features
First described in 1986, RBD, like sleepwalking, is associated with complicated behaviors during sleep such as walking, running, singing, and talking (Schenck and Mahowald 2005). In contrast to sleepwalking, which occurs during the first third of the night during delta sleep, RBD usually occurs during the second half of the night during REM sleep. It apparently occurs as a consequence of intermittent loss of the muscle atonia normally present in REM sleep, facilitating enacted dream motor activity. The movement activity that occurs is usually semi-purposeful, but may put the patient or bed partner at risk due to flailing or kicking arms or legs, or to the well-intentioned efforts of the sufferer to fight off assailants attacking in a dream.

Also, in contrast to sleepwalking, memory for the dream content is usually good in RBD. Furthermore, the idiopathic form typically occurs in men during the sixth or seventh decade of life. The cause or causes remain unknown. It has been reported in a variety of neurological disorders and during withdrawal from sedatives or alcohol; during treatment with tricyclic antidepressants or biperiden (Akineton); and in various neurological disorders including dementia, subarachnoid hemorrhage, and degenerative neurological disorders.

Treatment
Nocturnal administration of clonazepam, typically in a dose of between 0.5−1 mg, is usually remarkably successful in controlling the symptoms of this disorder. Patients and their families should be educated about the nature of the disorder and warned to take precautions about injuring themselves or others. Extended follow-up of patients with this disorder has also demonstrated that those presenting with this condition are at high risk for later development of neurodegenerative disorders, including Parkinson’s disease, multiple system atrophy, and dementia with Lewy body disease (Schenck and Mahowald 2005). Limited studies, typically performed open label in small case series, also suggest that MT in doses of between 3 and 12 mg at night may be effective for some patients who have not responded to treatment with clonazepam.

Sleep-Related Eating Disorders
Changes in sleep patterns may occur in patients with eating disorders. Night binging and increased sleep after eating are commonly reported in bulimic patients, who are also reported to eat and shop for food while sleepwalking. The patient frequently does not remember these nocturnal episodes; they often become known from family or friends who have observed the behavior or from physical evidence of shopping or eating behaviors. Patients with anorexia nervosa are often hyperactive, needing little sleep. Given the degree of physical and psychic stress associated with eating disorders, it is surprising how limited are the objective sleep disturbances associated with these disorders.

Questions have been raised in both the lay and scientific press about the possibility that hypnotic medications could play a role in promoting unwanted, “automatic” behaviors in sleep. In response, the FDA has advised manufacturers of a broad range of sleeping pills to warn patients that use of these medications may increase the potential for “complex sleep-related behaviors” which may include “sleep-driving, making phone calls and preparing and eating food (while asleep).” This is a real concern, but events of this sort appear to occur infrequently, especially in view of the large numbers of patients using these medications on a regular basis.

Sleep Disorders Due To a General Medical Condition
A sleep disorder due to a general medical condition is defined in DSM-IV-TR as a prominent disturbance in sleep severe enough to warrant independent clinical attention. Subtypes include insomnia, hypersomnia, parasomnia, and mixed types.

As a general rule, any disease or disorder that causes pain, discomfort, or a heightened state of arousal in the waking state is capable of disrupting or interfering with sleep (Sateia 2004). Examples of this phenomenon include pain syndromes of any sort, arthritic and other rheumatological disorders, prostatism and other causes of urinary frequency or urgency, chronic obstructive lung disease, and other pulmonary conditions. Many of these conditions increase in prevalence with advancing age, suggesting at least one reason that sleep disorders are more likely to be seen in senior populations. A few examples of sleep disorders due to general medical conditions follow.

Rheumatological Disorders
Rheumatological disorders often cause disturbances of sleep depth and continuity (Sateia 2004). The pain and discomfort associated with flares of rheumatoid arthritis lead to markedly disrupted sleep, with complaints of increased pain and stiffness the following day. Similar (although somewhat less intense) complaints are seen in association with untreated (or insufficiently treated) osteoarthritis. In both disorders, normal movements associated with shifts in position and stage in sleep may trigger awakenings from which return to sleep may be difficult or impossible. Similar problems may be seen with injuries to, or inflammation of, the back or ribs, with a report of awakening with pain associated with all shifts of position while asleep.

Fibromyalgia
Fibromyalgia is typically associated with complaints of chronic, relapsing fatigue with shallow, unrefreshing sleep and localized tenderness in different muscle groups (“trigger points”). No laboratory evidence of articular, nonarticular, musculoskeletal, or metabolic disease exists. Onset usually begins in young women. Although increased amounts of alpha-wave intrusion and disruption of other sleep stages have been described in some patients with fibromyalgia, this is not a uniform finding and is probably not important in the pathophysiological process (Sateia 2004).

Gastrointestinal Conditions
Sleep disturbance is particularly associated with peptic ulcer disease and gastroesophageal reflux (Sateia 2004), and rectal urgency in patients with colitis or ileitis. Patients with
Sleep in Elderly with Dementia
The sleep of older adults with dementia is extremely disturbed, with severely fragmented sleep, often to the extent that there is not a single hour in a 24-hr day that is spent fully awake or asleep (Pat-Horenczyk et al. 1998). Patients with mild to moderate dementia have extremely fragmented sleep at night, while those with severe dementia are extremely sleepless during both the day and night (Pat-Horenczyk et al. 1998). Sleep stages also change with dementia, with significantly lower amounts of Stages 3, 4, and REM sleep, and significantly more awakenings, as well as more time spent awake during the night. This results in increased Stage 1 sleep and decreased sleep efficiency (Ancoli-Israel et al. 2003a). It has also been shown that there is a high prevalence of sleep apnea in patients with dementia, with as many as 80% having symptoms that meet the criteria for diagnosis (Gehrmann et al. 2003). The sleep changes and disruption seen are likely due to the neuronal degeneration found in Alzheimer’s disease. Neuronal structures damaged in patients with dementia include the basal forebrain and the reticular formation of the brain stem, the same structures implicated in sleep regulation.

The nocturnal awakenings seen in dementia patients are often accompanied by agitation, confusion, and wandering. These behaviors have been referred to as “sundowning” as it was believed that they typically occurred as the sun set. It has been suggested that agitation or sundowning may be a circadian rhythm disorder (Bliwise et al. 1993, Martin et al. 2000). These authors found an association between circadian rhythms of activity, agitation and light exposure, indicating that sleep disruption in demented individuals may be amenable to treatment using bright light exposure. Others have tested this theory by exposing patients with dementia to bright light. The results have been mixed, but in general support the theory that increased light exposure, whether during the morning or evening, will improve both sleep and behavior to some extent (Ancoli-Israel et al. 2003b, McCurry and Ancoli-Israel 2003).

Parkinson’s Disease
Sleep difficulties are particularly common in patients with Parkinson’s disease with over half complaining of difficulty falling asleep and almost 90% complaining of difficulty staying asleep. Sleep recordings confirm that these patients, in fact, do have a prolonged sleep latency and are awake about one-third of the night. The sleep disruption may be secondary to the Parkinson’s disease itself or to the medication used to treat the disease. Neurochemical changes caused by the disease include reductions in serotonergic, noradrenergic, and cholinergic neurons, all of which are involved in sleep regulating mechanisms. Dopaminergic agents used to treat the disease affect sleep-wake patterns. Motor activity, including tremors, muscle contractions, increased muscle tone, vocalizations, and PLMS all disrupt sleep. Respiratory disorders, most common in patients with autonomic disturbance, are likely to contribute to sleep fragmentation. Finally, sleep-wake schedules are easily disrupted, either due to the medications, or to circadian rhythm abnormalities such as advanced or delayed sleep phase. Sleep disruption often increases with the progression of the disease (Arnulf et al. 2002).

Sleep hygiene education may improve sleep in patients with Parkinson’s disease. For example, since patients often complain of difficulty getting to the bathroom at night, having a commode available at the bedside may be extremely helpful. The spouse or bed partner might consider sleeping in a different bed since the patient’s disrupted sleep may impact the sleep of the bed partner. Since the bed partner is often also the caregiver, this sleep disruption may lead to early institutionalization. In addition to behavioral treatment of sleep problems, adjusting the time and dose of the dopaminergic medications used for treating Parkinson’s disease may improve the problem. Low doses in the evening may prevent insomnia but may not sufficiently control nocturnal rigidity. Higher evening doses will promote sleep by minimizing nocturnal rigidity, however, this may cause sleep-onset insomnia. Withdrawal from dopamine agonists may lead to severe akinesia, which is associated with sleep disruption. Some of the intermediate-acting sedative-hypnotics, such as clonazepam or temazepam, may improve the insomnia caused by nocturnal dyskinesia. The shorter-acting benzodiazepines, such as zolpidem or zaleplon, are also indicated to help stabilize the sleep-wake schedule. Sedating tricyclic antidepressants such as amitriptyline may improve both sleep-onset insomnia and some daytime Parkinsonian symptoms. However, since they can cause nocturnal delirium, they are contraindicated for cognitively impaired patients.

Dopaminergic agents taken in the evening can cause sleep-onset insomnia. Chronic use of L-dopa causes vivid dreams, nightmares, and night terrors, particularly with demented patients. Therefore, for Parkinson’s disease patients with dementia suffering from nocturnal hallucinations and confusion, only very small doses of L-dopa can be used, and the sleep disruption is particularly difficult to manage.

Substance-Induced Sleep Disorder
An important aspect of the evaluation of any patient, particularly those with sleep disorders, is the review of medications and other substances (including prescription, over-the-counter and recreational drugs, as well as alcohol, stimulants, narcotics, coffee and caffeine, and nicotine) and exposure to toxins, heavy metals, and so forth (Gillin et al. 2005). These substances may affect sleep and wakefulness during either ingestion or withdrawal, causing most commonly insomnia, hypersomnia, or, less frequently, parasomnia or mixed types of difficulties. On the basis of DSM-IV-TR criteria, a diagnosis of substance-induced sleep disorder may be made if the disturbance of sleep is sufficiently severe to warrant independent clinical attention and is judged to result from the direct physiological effects of a substance. Substance-induced sleep disorder should only be diagnosed if the sleep disturbance is not better accounted for by a mental disorder and does not occur during delirium. If appropriate, the context for the development of sleep symptoms may be
Substance-Induced Sleep Disorder

A. A prominent disturbance in sleep that is sufficiently severe to warrant independent clinical attention.

B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):
   (1) the symptoms in criterion A developed during, or within a month of, substance intoxication or withdrawal
   (2) medication use is etiologically related to the sleep disturbance

C. The disturbance is not better accounted for by a sleep disorder that is not substance induced. Evidence that the symptoms are better accounted for by a sleep disorder that is not substance induced might include the following: the symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication, or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence that suggests the existence of an independent nonsubstance-induced sleep disorder (e.g., a history of recurrent nonsubstance-related episodes).

D. The disturbance does not occur exclusively during the course of a delirium.

E. The sleep disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Note: This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the sleep symptoms are in excess of those usually associated with the intoxication or withdrawal syndrome, and when the symptoms are sufficiently severe to warrant independent clinical attention.

Code

[specific substance]-induced sleep disorder:
(291.8 alcohol; 292.89 amphetamine; 292.89 caffeine; 292.89 cocaine; 292.89 opioid; 292.89 sedative, hypnotic, or anxiolytic; 292.89 other [or unknown] substance)

Specify type:

Insomnia type: if the predominant sleep disturbance is insomnia

Hypersomnia type: if the predominant sleep disturbance is hypersomnia

Parasomnia type: if the predominant sleep disturbance is a parasomnia

Mixed type: if more than one sleep disturbance is present and none predominates

Specify if:

With onset during intoxication: if criteria are met for intoxication with the substance and the symptoms develop during the intoxication syndrome

With onset during withdrawal: if criteria are met for withdrawal from the substance and the symptoms develop during, or shortly after, a withdrawal syndrome

indicated by specifying with onset during intoxication or with onset during withdrawal.

The recognition of substance-related sleep disturbances usually depends on active searching by the psychiatrist, beginning with a careful history, physical examination, laboratory and toxicological testing, and information (with permission) from former health care providers or friends and relatives. Patients may not know what prescription medications they are taking or the doses, and may forget to mention over-the-counter medications, coffee, occupational or environmental toxins, and so forth. In the case of alcohol and drugs of abuse, they may deny to themselves and others their use, or quantity, or frequency of use. Substance dependence and abuse is often associated with other psychiatric diagnoses or symptoms. When comorbidity does exist, it is important to establish, if possible, whether the sleep disturbance is primary or secondary, that is, whether the sleep disturbance is substance-induced (secondary) or whether the substance use functions as a form of “self-medication” for sleep disturbance, in which the sleep disturbance would be considered primary. Many patients with alcoholism experience secondary depression during the first few weeks of withdrawal from alcohol and exhibit short REM latency and other sleep changes similar to those reported in primary depression. This secondary depression usually remits spontaneously. Likewise, about one-third of patients with unipolar depression and about three-fifths of patients with bipolar disorder, manic type, have a substance use pattern that meets diagnostic criteria for alcoholism or substance abuse at some point. Prognosis and treatment may be altered in comorbid states, depending on whether the sleep disturbance is primary or secondary. In general, treatment should be aimed at the primary diagnosis after management of any acute withdrawal condition that may exist.

Alcohol

Alcohol is probably the most commonly self-administered “sleeping aid.” Although it may be sedating, especially in middle-aged or elderly or sleep-deprived persons, its usefulness as a hypnotic is limited by potential disinhibiting and
Nicotine

Avoiding any type of sleep disturbance has been attributed to the effects of alcohol or alcohol withdrawal in patients with alcohol abuse or dependence. Insomnia may occur during episodes of drinking and acute and chronic withdrawal. Complaints of insomnia and objective disruption of sleep continuity and Stages 3 and 4 sleep have been reported for up to several years in some abstinent patients. Hypersomnia may occur during heavy bouts of drinking, sometimes with peripheral compression neuropathies, or as “terminal hypersomnia” after delirium tremens. Circadian sleep disturbances may also occur during bouts of drinking, including periods of short polyphasic sleep–wake episodes. Parasomnias include sleepwalking and enuresis.

Because alcohol may temporarily improve the poor sleep of the chronic alcoholic individual, sleep disturbance may be a factor in relapse (Landolt and Gillin 2001). Treatment of the sleep disturbances of the chronic alcoholic individual is difficult. Nonpharmacological approaches include sleep hygiene and sleep restriction, as well as attention to general nutrition, physical health, and psychosocial support. Use of benzodiazepines or other hypnotics is not generally recommended because of cross-tolerance or deliberate or inadvertent overdose. It has been reported that increased REM percentage and short REM latency at admission to an inpatient alcohol treatment program are risk factors for relapse in primary alcoholic patients without depression (Gillin et al. 1994).

Sedatives, Hypnotics, and Anxiolytics

Tolerance to the sedating effects of barbiturates, chloral hydrate, and even benzodiazepines usually develops with repeated administration. This is true especially with short half-life agents, with the possible exception of zolpidem. One or two days of withdrawal insomnia may occur after a few days of administration of short half-life benzodiazepines, such as triazolam, but not with the newer nonbenzodiazepine hypnotics, such as zolpidem and zaleplon.

</table>
Potential side effects associated with sedating medications during the sleep period include falls and fractures, difficulty arousing to the telephone or the crying infant, amnesia, impairment of cognitive and motor skills, drug-induced sleepwalking, and possibly, BRSDs.

Other Substances

Many medications produce sleep disturbance, including those with central or autonomic nervous system effects, like adrenergic agonists and antagonists, dopamine agonists and antagonists, cholinergic agonists and antagonists, antihistamines, and steroids. Among the prescription drugs associated frequently with sleep disorders are the SSRIs, which have been connected with overarousal and insomnia in some patients and, more commonly, sedation in other patients. Additional sleep-related disturbances occasionally associated with the SSRIs include sleepwalking, RBD, and REMs during NREM sleep.

Clinical Vignette 1

When first seen in evaluation, Mr. SV was a 48-year-old married male with a chief complaint of leg, arm, and occasional body jerking throughout the night, which caused awakenings and led to lightened and fragmented sleep. He also reported restlessness in his legs at sleep onset, interfering with his capacity to fall asleep. He reported that it typically took him 40 min to fall asleep, but that occasionally his initial sleep latency could be as long as 2 hr. He would typically awaken four to five times per night, then have difficulty falling back to sleep.

He reported that symptoms had been present for about 7 years, but had become much worse in the 2 months prior to his evaluation. He questioned whether this might have resulted from a more active exercise schedule that he had undertaken in an effort to lose weight.

Mr. SV reported that his sleep in recent weeks had been disrupted to the extent that he was sleeping only 4−5 hr per night. This reflected a significant decrease from his historic average of 7 hr of sleep per night. However, he denied any sleepiness as a consequence of his disturbed sleep, reporting an Epworth Sleepiness Scale Score of 0, consistent with no perceived hypersomnia tendencies.

He reported mild snoring but denied awareness of pauses in breathing. His wife confirmed the absence of any episodes of the “breath-holding” suggestive of sleep apnea. She confirmed the presence of “restless sleep,” with frequent twitches and jerks of the arms and legs, which disrupted her sleep, as well as that of her husband.

Mr. SV reported a history of asthma, not requiring treatment with medication at that time. He denied any other significant health problems, specifically denying a history of anemia or of any type of kidney disease. Physical examination was normal, with a normal body mass index and neck circumference, and with a normal-appearing oral airway.

The presumptive diagnosis at this time was RLS and PLMS. A trial of L-dopa/carbidopa was initiated at a dose of 25/100 mg, with directions to increase the dose as needed.

Three weeks later, Mr. SV reported an excellent response at the initial dose of 25/100 taken 2 hr before bedtime, with a reported sleep latency of 5–10 min, and a reduction in awakenings to two to three times per night.

When he did wake up in the night, he reported that he could fall back to sleep without great difficulty.

Over the next 6 months, Mr. SV reported the need for a progressive increase in doses of L-dopa/carbidopa, to the point where he was taking 3 tablets of the 25/100 mg dose. He was beginning to experience an increase in sensations of restlessness prior to his evening dose of medication, as well as a return of movement symptoms in the early morning hours.

Rather than a further increase in medications, Mr. SV requested a trial of a different medication. He was instructed to discontinue the L-dopa/carbidopa and was started on pramipexole 0.125 mg, with instructions to begin with 1 tablet 1 hr before bedtime for 5 days, and to increase up to 2 tablets as needed. He experienced initial benefit at the dose of 2 × 0.125 mg, with sustained sleep throughout the night and no complaints of restlessness at the start of the night.

He continued to do well with this regimen for 6 months. At that time he noted a return of some symptoms of restlessness and movement activity disrupting sleep. The dose was raised to 3 × 12.5 mg, (with good symptomatic relief). He has remained symptom-free at this dose, with no complaints of side effects or intolerance of the medication.

Discussion

Mr. SV presented with a typical RLS/PLMS history, although many patients with these complaints that have persisted over a longer period of time will also complain of daytime fatigue or sleepiness.

No sleep studies were performed. Although it would have been of interest to confirm the clinical diagnosis of RLS/PLMS with a polysomnographic study, there were no symptoms present suggestive of another disorder, such as sleep apnea, which could have caused his complaints and which could have been confirmed or excluded on the basis of PSG.

Had he not responded to a first or second course of pharmacologic therapy for his presumed RLS/PLMS, a sleep study could have been ordered to confirm the diagnosis.

From a historical perspective, the absence of anemia or of kidney disease were of importance to rule out treatable causes of RLS/PLMS (iron deficiency or renal failure). However, treatment for these conditions (iron replacement or dialysis) does not always lead to resolution of the RLS/PLMS complaints, particularly in early phases of treatment for iron deficiency anemia.

The history of loss of benefit from treatment with L-dopa/carbidopa is also not unusual. Patients taking this medication often experience a “breakthrough” of RLS symptoms over time, and may report that, as medication is given earlier in the evening to reduce symptoms of restlessness, symptoms begin to appear progressively earlier, frustrating efforts at effective treatment.

Clinical Vignette 2

When seen in consultation, Ms. A was a 56-year-old married woman, the wife of a physician, referred by her rheumatologist for evaluation of long-standing sleep complaints. She described her sleep complaint as follows: “With the help of medications, I am able to sleep for 2–4 hr. When I wake up, I am fully awake no matter what the hour.”
She stated that her sleep problems had been present for approximately 15 years. She described in great detail her severe problems with fibromyalgia, which had led to a substantial decline in functioning. She reported that she had experienced a significant degree of improvement under the care of her rheumatologist and noted that sedating antidepressants, particularly amitriptyline, had been helpful to her in controlling pain and improving her sleep. Other antidepressants that had been used singly or in combination included doxepin and nortriptyline. Cyclobenzaprine had been of some benefit but led to a complaint of mouth dryness. She had received various sedative medications in treatment of sleep complaints, including clonazepam, triazolam, temazepam, chloral hydrate, meprobamate, ethchlorvynol, and various barbiturates. In reviewing her history of hypnotic use, it became apparent that she had in fact used hypnotic medications on a nightly basis for more than 30 years. She had also used L-tryptophan in the past and had experienced a well-documented cosinophilic—myalgia syndrome, presumably associated with contaminants in L-tryptophan sold as a “food additive.”

She reported that she took her sleep medication (at time of evaluation, temazepam at 30 mg) 2–2.5 hr before her regular hour of retiring at 11 PM. She awakened several hours later without awareness of any specific cause and reported difficulty in returning to sleep on a nightly basis. She listened to a tape recorder on a nightly basis, using self-help and relaxation tapes and keeping the recorder running throughout the night whether she was awake or asleep.

She reported that she “rested” for an hour at a time several times a day, although she denied feeling truly sleepy at any point in the daytime, acknowledging instead symptoms of fatigue and low energy. She acknowledged that “on rare occasions,” she might briefly fall asleep during these periods of daytime rest.

A Minnesota Multiphasic Personality Inventory was performed a year before evaluation and demonstrated an elevation in the depression (D) scale. No formal psychiatric treatment had been recommended or obtained.

PSG was considered, but not obtained. PSG is typically not obtained as part of the initial evaluation of the insomnia patient. When the PSG demonstrates poor sleep—a low sleep efficiency—it confirms the patients subjective complaint but may not suggest a specific therapeutic intervention. When the PSG demonstrates relatively good sleep—a normal sleep efficiency—the patient is likely to report that this was a “better night than normal,” unusual but occasionally experienced.

Although positive findings from a PSG are helpful for some patients, for example, when sleep apnea or leg movement activity is discovered, a PSG is usually reserved for patients who have atypical complaints, symptoms suggestive of a primary sleep disorder such as sleep apnea, and those who have failed multiple trials of pharmacotherapy, combined with behavioral and cognitive interventions.

Treatment for Ms. A was initiated to reduce reliance on medications, to improve sleep hygiene, and to improve nocturnal sleep continuity. Use of her tape recorder during the night was forbidden because it may have activated her, and her sleep medication was changed to zolpidem to allow for more rapid onset of action and shorter duration of action. She was instructed to discontinue her periods of rest during the daytime, with the exception of a single 20-min period of rest or sleep in the afternoon. She was told not to go to bed until she felt tired in the evening and to take her sleep medication at that time. She was instructed to avoid clock watching during the night and to read something relaxing or boring in another room until she felt sleepy, at which point she could return to bed. She was asked to complete a sleep diary on a daily basis. Her initial perception was of somewhat less sleep than she had previously been obtaining, with a further decline in daytime performance. In a period of 4 weeks, her reported sleep time at night climbed to 5 hr, with improvement in perceived daytime function. After a year of further support of behavioral interventions and good sleep hygiene, she was able to taper and discontinue use of hypnotics and antidepressants, reported a substantial improvement in her fibromyalgia complaint, and had essentially complete resolution of her sleep complaints.

Clinical Vignette 3

When seen in consultation, Mr. O was a 61-year-old married male attorney, seen alone, who presented for evaluation of complaints of snoring and observed pauses in breathing. His wife had reported to him her observation of very loud, continuous snoring and clear-cut sleep apnea episodes. On occasion, the snoring was loud enough that his wife needed to go sleep in a guest bedroom. Mr. O was aware, on occasion, of waking during the night due to snoring, but did not report awareness of any apneas. He had no difficulty initiating sleep at the start of the night, and would often fall asleep watching television in the evening.

Mr. O reported that he did not feel fully restored or refreshed upon awakening in the morning, and that he would wake up several times during the night, usually with the need to go to the restroom. He denied urinary frequency in the daytime. He did report waking with a dry mouth during the night and in the morning, but not of a morning headache. He did report occasional problems with gastroesophageal reflux waking him during the night.

Mr. O acknowledged some reductions in concentration, memory, and attention during the day. He reported that he had experienced some increase in irritability and that he felt that his energy level was somewhat reduced relative to the past. He acknowledged some tendencies to excessive sleepiness when sedentary. He completed an Epworth Sleepiness Scale questionnaire which resulted in a score of 12, which was in the mildly elevated range. However, this likely reflected an underestimation of the severity of actual sleepiness.

Mr. O reported a benign medical history with no significant medical problems. However, his blood pressure had been observed to be “creeping up” when checked recently. He had a history of depression dating back many years, and was taking Wellbutrin with some benefit but without complete resolution of depressive symptoms. He denied taking any other medications on a regular basis. He did not smoke, and reported limited use of alcohol and caffeine containing beverages. He acknowledged that use of alcohol made his snoring worse, and that he occasionally used caffeine to increase alertness during the day.

He denied any history of injuries to or surgery involving the nose, throat, neck, or jaw, or any history of allergies. He noted that his father probably had sleep apnea, and that other relatives had been loud snorers.
On physical examination, Mr. O weighed 236 pounds fully clothed, carried on an approximate 5' 10" frame. Body habitus was obese (body mass index (BMI) = 34). The neck circumference was 18.5 inches, with a very full submentobular space. Nasal flow was equal bilaterally without obvious constriction. Facial structure was not noteworthy for a foreshortened jaw. Examination of the oropharynx demonstrated a crowded airway outlet.

Mr. O recognized that sleep apnea likely was present, but expressed concern about his ability to tolerate nasal CPAP if studies suggested that it would be appropriate therapy for him. PSG was performed. Mr. O demonstrated moderate obstructive sleep apnea-hypopnea, with an index of 24.8 events per hour for total sleep time, 11.9 events per hour in NREM sleep, and 49.2 events per hour in REM sleep. Apnea was also more severe in the supine position (Supine AHI = 32.5). ECG showed mild acceleration-decelerations with obstructive breathing events, but otherwise was unremarkable.

After a review of the study results, Mr. O agreed to a CPAP titration study, which documented that effective treatment of his sleep apnea could be attained at a CPAP pressure setting of 10 cm H2O. He had little difficulty tolerating CPAP, indicated that the CPAP mask was properly fitted and that CPAP was comfortable, and stated that he would “absolutely” use it as therapy if prescribed. He rated his sleep quality with CPAP as much better than a normal night’s sleep at home.

CPAP treatment was initiated, and Mr. O was quite successful with his adaptation to CPAP, as measured by records of hours of use obtained from his CPAP unit. He reported an immediate improvement in his perceptions of sleep quality, energy and cognitive function, and reported a progressive improvement in mood with functional absence of depressive symptoms.

He has continued to use nasal CPAP on a nightly basis for two years, with stability in mood, cognitive function and energy levels, and without continued in creases in blood pressure. He has expressed a desire to work on weight reduction, but has not attained any persistent weight loss.

Comparison of DSM-IV-TR / ICD-10 Diagnostic Criteria

For primary insomnia, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical except that ICD-10 requires a frequency of at least three times a week for at least a month, whereas DSM-IV-TR does not specify a required frequency. For primary hyper insomnia, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical except that ICD-10 also counts sleep drunkenness as a presenting symptom. Furthermore, ICD-10 requires that the problems occur nearly every day for at least 1 month (or recurrently for shorter periods of time).

Since narcolepsy and BRSD are included in chapter VI (Diseases of the Nervous System) in ICD-10, there are no diagnostic criteria provided for these conditions.

For circadian rhythm sleep disorder, the ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria are almost identical except that ICD-10 specifies that the problems occur nearly every day for at least 1 month (or recurrently for shorter periods of time) (DSM-IV-TR has no specified duration). This condition is referred to in ICD-10 as “Nonorganic disorder of the sleep–wake cycle.”

The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria for nightmare disorder and sleepwalking disorder are essentially identical. The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria sets for sleep terror disorder are almost identical except that ICD-10 explicitly limits the duration of the episode to less than 10 min.

Introduction
Although dissimilar in behavioral expressions, the disorders in this chapter share the feature of impulse dyscontrol. Individuals who experience such dyscontrol are overwhelmed by the urge to commit certain acts that are often apparently illogical or harmful (McElroy et al. 1992). Whereas impulse-control disorders (ICDs) were once conceptualized as either addictive or compulsive behaviors, they are now classified within the DSM-IV-TR (American Psychiatric Association 2000) ICD category. These include intermittent explosive disorder (IED) (failure to resist aggressive impulses), kleptomania (failure to resist urges to steal items), pyromania (failure to resist urges to set fires), pathological gambling (failure to resist urges to gamble), and trichotillomania (failure to resist urges to pull one’s hair). It should be noted that behaviors characteristic of these disorders may be notable in individuals as symptoms of another mental disorder. If the symptoms progress to such a point that they occur in distinct, frequent episodes and begin to interfere with the person’s normal functioning, they may then be classified as a distinct ICD.

There are also a number of other disorders that are not included as a distinct category but are categorized as ICDs not otherwise specified in DSM-IV-TR. These include sexual compulsions (impulsive-compulsive sexual behavior), compulsive shopping (impulsive-compulsive buying disorder), skin picking (impulsive-compulsive psychogenetic excoriation), and internet addiction (impulsive-compulsive computer usage disorder). These disorders are unique in that they share features of both impulsivity and compulsivity and might be labeled as ICDs. Patients with these disorders engage in the behavior to increase arousal. However, there is a compulsive component in which the patient continues to engage in the behavior to decrease dysphoria.

To properly conceptualize ICDs, it is helpful to understand the role of impulsivity within them. The trait of impulsivity has been the subject of increasing interest in psychiatry. Impulsivity is a defining characteristic of many psychiatric illnesses, even those not classified as ICDs, including Cluster B personality disorders like borderline personality disorder (BPD) and antisocial personality disorder (ASPD), neurological disorders characterized by disinhibited behavior, attention-deficit/hyperactivity disorder (ADHD), substance and alcohol abuse, conduct disorder, binge-eating, bulimia, and paraphilias. Impulsivity research has been conducted both in disorders characterized by impulsivity, like BPD, ASPD, and conduct disorder, and in traditional ICDs like IED. Clinicians should recognize that individuals who are prone to impulsivity and ICDs are often afflicted with a cluster of related conditions including sexual compulsions, substance use disorders, and posttraumatic stress disorder and to screen for comorbid conditions such as bipolar spectrum disorders and ADHD that contribute to impulsivity (Figure 80–1).

Impulsivity is the failure to resist an impulse, drive, or temptation that is potentially harmful to oneself (e.g. trichotillomania, pathological gambling) or others (e.g. IED, pyromania, kleptomania) is a common clinical problem and

Figure 80–1 Differential diagnosis of impulsivity. Impulsivity is a tendency to act in a sudden, unpremeditated, and excessively spontaneous fashion. Other decision trees that should be considered are those for aggressive behavior, catatonia, delusions, depressed mood, euphoric or irritable mood, disorganized or unusual behavior, distractibility, eating behavior, self-mutilation, and suicide ideation or attempt. (NOS, not otherwise specified.)
a core feature of human behavior. An impulse is rash and lacks deliberation. It may be sudden and ephemeral, or a steady rise in tension that may reach a climax in an explosive expression of the impulse, which may result in careless actions without regard to the consequences to self or others. Impulsivity is evidenced behaviorally as an underestimated sense of harm, carelessness, extroversion, impatience, including the inability to delay gratification, and a tendency toward risk taking, and sensation seeking (Hollander et al. 2002). What makes an impulse pathological is the person’s inability to resist it and its expression.

New research findings associate various forms of impulsive behavior with biological markers of altered serotonergic function. These include impulsive suicidal behavior, impulsive aggression, and impulsive fire setting (Stein et al. 1993). In all these circumstances, impulsivity is conceived of as the rapid expression of unplanned behavior, occurring in response to a sudden thought. (This is seen by some as the polar opposite of obsessional behavior, in which deliberation over an act may seem never ending.) Although the sudden and unplanned aspect of the behavior may be present in the impulse disorders (such as in IED and kleptomania), the primary connotation of the word impulsivity, as used to describe these conditions, is the irresistibility of the urge to act. In DSM-IV-TR, ICDs are characterized by five stages of symptomatic behavior (Table 80–1). First is the increased sense of tension or arousal, followed by the failure to resist the urge to act. Third, there is a heightened sense of arousal. Once the act has been completed, there is a sense of relief and remorse at having committed the act. In conditions like trichotillomania, pyromania, and pathological gambling, the individual may spend considerable amounts of time fighting off the urge, trying not to carry out the impulse. The inability to resist the impulse is the common core of these disorders, rather than the rapid transduction of thought to action. A decision tree for the differential diagnosis of impulsive behaviors may be seen in Figure 80–1.

Other than sharing the essential feature of impulse dyscontrol, it is unclear whether the conditions in this chapter bear any relationship to each other. Emerging perspectives on the neurobiology of impulsivity suggest that impulsive behaviors, across diagnostic boundaries, may share an underlying pathophysiological diathesis. As noted earlier, markers of altered serotonergic neurotransmission have been associated with a variety of impulsive behaviors: suicidality, aggressive violence, pyromania, and conduct disorder. These observations have led to speculation that decreased serotonergic neurotransmission may result in decreased ability to control urges to act. In accord with this model, these disorders may be varying expressions of a single disturbance—or closely related disturbances—of serotonergic function. Although such markers of altered serotonergic function have been demonstrated among impulsive fire setters and impulsive violent offenders, there is, as yet, insufficient research on these conditions to accept or dismiss this theory.

It has been noted that these conditions are embedded in similar patterns of comorbidity with other psychiatric disorders. High rates of comorbid mood disorder and anxiety disorder appear typical of these disorders. This contextual similarity, combined with the common feature of impulsivity, may further support the notion that these conditions are—at the level of core diathesis—related to each other.

Although these conditions have historically been considered uncommon, later investigations suggest that some of them may be fairly common. Trichotillomania, for example, was once considered rare. However, surveys indicate that the lifetime prevalence of the condition may exceed 1% of the population. Pathological gambling may be present in up to 3% of the population. Extrapolation from the known incidence of comorbid conditions suggests that kleptomania may have a 0.6% incidence. It would seem reasonable to suspect that individuals with pyromania and kleptomania may seek to avoid detection and may therefore be underrepresented in research and clinical samples.

Few treatment studies of these specific conditions have been conducted. Attempts to treat these conditions are usually formulated by extrapolation from treatments that have been developed for other conditions. The treatment literature for most of these conditions reflects the general development of psychiatric therapy. Papers from the early part of the 20th century are largely restricted to reports of the psychoanalytic treatment of individual cases or of small series. The aggressive quality of kleptomania, pyromania, and IED and the self-damaging nature of trichotillomania and pathological gambling have presented tempting substrates for the application of traditional analytical concepts. From this perspective, these behaviors have been seen as symptomatic expressions of unconscious conflict, often sexual in nature. Other formulations include desires for oral gratification and

masochistic wishes to be caught and punished, motivated by a harsh, guilt-inducing superego. The increasing influence of object relations theory was reflected in increasing emphasis on narcissistic psychopathology and histories of disturbed early parenting. As successful behavioral interventions were developed for other conditions, case reports of behavioral treatments for these conditions emerged. Reports of hypnagogic treatments are also prominent in the literature.

As pharmacological treatments are applied to an increasing range of symptoms, the ICDs in this chapter present new opportunities to widen the application of thymoleptic and anxiolytic and, more recently, atypical neuroleptic medication. As part ongoing evolving theory, the very concept of impulsivity is still in ferment. Attempts to further refine the idea of impulsivity are reflected in a perspective offered by Van Ameringen et al. (1999).

Trichotillomania, IED, and pathological gambling have become the focus of increasing interest of late. However, kleptomania and pyromania remain stepchildren of research. Perhaps the legal implications of these behaviors have become the focus of increasing interest of late. How-ever, kleptomania and pyromania remain stepchildren of research. Perhaps the legal implications of these behaviors and their entanglement with similar—but not impulsively research. Because of the limited body of systematically collected data, the following sections largely reflect accumulated clinical experience. Therefore, the practicing psychiatrist should be particularly careful to consider the exigencies of individual patients in applying treatment recommendations.

**Intermittent Explosive Disorder**

**Definition and Diagnostic Features**

IED is a DSM diagnosis used to describe people with pathological impulsive aggression (see box for diagnostic criteria).

---

### DSM-IV-TR Criteria

**Intermittent Explosive Disorder**

A. Several discrete episodes of failure to resist aggressive impulses that result in serious assaultive acts or destruction of property.

B. The degree of aggressiveness expressed during the episodes is grossly out of proportion to any precipitating psychosocial stressors.

C. The aggressive episodes are not better accounted for by another mental disorder (e.g., antisocial personality disorder, borderline personality disorder, a psychotic disorder, a manic episode, conduct disorder, or attention-deficit/hyperactivity disorder) and are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., head trauma, Alzheimer's disease).

---

Impulsive aggression, however, is not specific to IED. It is a key feature of several psychiatric disorders and nonpsychiatric conditions and may emerge during the course of yet other psychiatric disorders. Therefore, the definition of IED as formulated in the DSM-IV-TR is essentially a diagnosis of exclusion. As described in criterion C, a diagnosis of IED is made only after other mental disorders that might account for episodes of aggressive behavior have been ruled out. The individual may describe the aggressive episodes as “spells” or “attacks.” The symptoms appear within minutes to hours and, regardless of the duration of the episode, may remit almost as quickly. As in other ICDs, the explosive behavior may be preceded by a sense of tension or arousal and is followed immediately by a sense of relief or release of tension.

Although not explicitly stated in the DSM-IV-TR definition of IED, impulsive aggressive behavior may have many motivations that are not meant to be included within this diagnosis. IED should not be diagnosed when the purpose of the aggression is monetary gain, vengeance, self-defense, social dominance, or expressing a political statement or when it occurs as a part of gang behavior. Typically, the aggressive behavior is ego-dystonic to individuals with IED, who feel genuinely upset, remorseful, regretful, bewildered, or embarrassed about their impulsive aggressive acts. Because the essential feature of IED is the occurrence of serious assaultive acts or destruction of property, it is a diagnosis relevant to the interface between psychiatry and the law.

Many clinicians and researchers rarely consider the diagnosis of IED, although impulsive aggressive behavior is relatively common. In community surveys, 12-25% of men and women in the United States reported engaging in physical fights as adults, a frequent manifestation of impulsive aggression (Robins and Regier 1992). Impulsive aggressive behavior is usually pathological and causes substantial psychosocial distress/dysfunction (McElroy et al. 1998). Being the recipient of impulsive aggressive behavior can lead to similar behavior in children who grow up in this environment (Huesmann et al. 1984).

Violence is underreported in Western societies. As discussed by Lion (1992) although violence is commonly encountered in clinical psychiatric practice, its diagnostic acknowledgment within psychiatry has always been problematic (McElroy et al. 1992). To a large extent, this difficulty also reflects history: Freud himself never fully developed a theory of aggression and came to consider the existence of a “primary” destructive drive only late in his life, after the death and devastation of World War I (Beyond the Pleasure Principle, published in 1920) (Freud 1955).

Episodes of violent behavior appear in several common psychiatric disorders such as ASPD, BPD, and substance use disorders and need to be distinguished from the violent episodes of patients with IED, which are apparently rare. The study of Felthous et al. (1991) in which 15 men with rigorously diagnosed DSM-III-R IED were identified from among a group of 443 men who complained of violence, permitted some systematic observations about the “typical violent episode” as reported by patients with IED.

In the vast majority of instances, the subjects with IED identified their spouse, lover, or girl/boy friend as a provocateur of their violent episodes. Only one was provoked by a stranger. For most, the reactions occurred immediately and without a noticeable prodromal period. Only one subject
stated that the outburst occurred between 1 and 24 hours after the perceived provocation. All subjects with IED denied that they intended the outburst to occur in advance. Most subjects remained well oriented during the outbursts, although two claimed to lose track of where they were. None lost control of urine or bowel function during the episode. Subjects reported various degrees of subjective feelings of behavioral dyscontrol. Only four felt that they completely lost control. Six had good recollection of the event afterward, eight had partial recollection, and one lost memory of the event afterward. Most IED subjects tried to help or comfort the victim afterward.

Assessment

Psychiatric Examination and History

The DSM-IV-TR diagnosis of IED is essentially a diagnosis of exclusion, and the psychiatrist should evaluate and carefully rule out more common diagnoses that are associated with impulsive violence. The lifelong nonremitting history of impulsive aggression associated with ASPD and BPD, together with other features of antisocial behavior (in ASPD) or impulsive behaviors in other spheres (in BPD) may distinguish them from IED, in which baseline behavior and functioning are in marked contrast to the violent outbursts. Other features of BPD such as unstable and intense interpersonal relationships, frantic efforts to avoid abandonment, and identity disturbance may also be elicited by a careful history. More than in most psychiatric diagnoses, collateral information from an independent historian may be extremely helpful, especially in forensic settings. Of note, patients with IED are usually genuinely distressed by their impulsive aggressive outbursts and may voluntarily seek psychiatric help to control them. In contrast, patients with ASPD do not feel true remorse for their actions and view them as a problem only to control them. In many subjects with ASPD, the psychiatrist may be able to generate only an impression that the subject is profiting from his or her aggression.

Other causes of episodic impulsive aggression are substance use disorders, in particular alcohol abuse and intoxication. When the episodic impulsive aggression is associated only with intoxication, IED is ruled out. However, IED and alcohol abuse may be related, and the diagnosis of one should lead the psychiatrist to search for the other.

Neurological conditions such as dementia, focal frontal lesions, partial complex seizures, and postconcussive syndrome after recent head trauma may all present as episodic impulsive aggression and need to be differentiated from IED. Other neurological causes of impulsive aggression include encephalitis, brain abscess, normal-pressure hydrocephalus, subarachnoid hemorrhage, and stroke. In these instances, the diagnosis would be personality change associated with episodic impulsive aggression but not diagnostic of a particular disorder and those, which suggest the diagnosis of a psychiatric or medical disorder other than IED.

The physical and laboratory findings relevant to the diagnosis of IED and the differential diagnosis of impulsive aggression may be divided into two main groups: those associated with episodic impulsive aggression but not diagnostic of a particular disorder and those, which suggest the diagnosis of a psychiatric or medical disorder other than IED. No laboratory or physical findings are specific for IED.

In the first group of findings that are associated with impulsive aggression across a spectrum of disorders includes soft neurological signs such as subtle impairments in hand-eye coordination and minor reflex asymmetries. These signs may be elicited by a comprehensive neurological examination and simple pencil-and-paper tests such as parts A and B of the Trail Making Test. Measures of central serotonergic function such as cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) levels, the fluramine challenge test, and positron emission tomography (PET) of prefrontal metabolism also belong to this group. Although these measures advanced our neurobiological understanding of impulsive aggression, their utility in the diagnosis of individual cases of IED and other disorders with impulsive aggression is yet to be demonstrated.

The second group of physical and laboratory findings is useful in the diagnosis of causes of impulsive aggression other than IED. The smell of alcohol on a patient’s breath or a positive alcohol reading with a Breathalyzer may help reveal alcohol intoxication. Blood and urine toxicology screens may reveal the use of other substances, and track marks on the forearms may suggest intravenous drug use. Partial complex seizures and focal brain lesions may be evaluated by EEG and brain imaging. In cases without a grossly abnormal neurological examination, magnetic resonance imaging may be more useful than computed tomography of the head. Magnetic resonance imaging can reveal mesiotemporal scarring, which may be the only evidence for a latent seizure disorder, sometimes in the presence of a normal or inconclusive EEG. Diffuse slowing on the EEG is a nonspecific finding that is probably more common in, but not diagnostic of, patients with impulsive aggression. Hypoglycemia, a rare cause of impulsive aggression, may be detected by blood chemistry screens.

Epidemiology

IED has been subjected to little systematic study. As formulated in DSM-IV-TR, IED is probably a rare disorder. The exclusionary criterion in the DSM-IV-TR definition (criterion C) reflects an ongoing debate over the boundaries of this disorder. The current definition of IED is the result of a succession of attempts by researchers to classify syndromes associated with impulsive aggression. The diagnostic term “IED” first appeared in the 1980 Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III). The DSM-III and the revised third edition (DSM-III-R) definitions of IED required the absence of signs of generalized impulsivity or aggressiveness between episodes. Episodic behavioral disorders are quite common and exist across a continuum between ictal causes (excessive neuronal discharges) and purely motivational causes (psychogenic).
Temper proneness is a relatively common clinical syndrome that is associated with a wide variety of psychiatric disorders and is usually found in patients with central nervous system dysfunction, character disorders, and psychotic substance abuse. “Pure” IED, on the other hand, was found to be a rare clinical entity.

A number of studies have looked at clinical populations, and one community survey has been done to determine the prevalence of IED. Numbers range between 1.1% and 6.3%. The evaluation of studies is complicated by the variety of defining criteria used, from DSM-III to current research criteria. Zimmerman et al. (1998) used the Structured Clinical Interview for DSM-IV to study current or lifetime IED in 411 psychiatric outpatients. They reported a rate of 3.8% for current IED and 6.2% for lifetime IED by DSM-IV criteria. A recent reanalysis of a much larger sample from the same population revealed similar rates of IED (Coccaro et al. 2005). Further, data from a pilot community sample study revealed a community rate of lifetime IED by DSM-IV-TR criteria at 4% and by IED-integrated research criteria at 5.1% (Coccaro et al. 2004). Considering the rates found in these more recent studies, IED could be as common as other major psychiatric disorders like schizophrenia or bipolar illness. In fact, the National Comorbidity Survey Replication (NCS-R) study found that IED is much more common than previously thought. Lifetime and 12-month prevalence estimates of DSM-IV IED were 7.3% and 3.9%, with a mean 43 lifetime attacks resulting in 1359 dollars in property damage. IED-related injuries occurred 180 times per 100 lifetime cases (Kessler et al. 2006).

In one study of the prevalence of DSM-III-R IED among violent men, Felthous et al. (1991) found that of 443 subjects who complained of violence, only 15 (3.4%) met criteria for IED. The DSM-III-R definition of IED was more restrictive than the current DSM-IV-TR diagnosis because it required the absence of signs of generalized impulsivity or aggressiveness between episodes. The EEGs of 13 of the men with IED were normal; two showed excessive slowing.

Most of the limited published data on gender differences suggest that males outnumber females with IED, and men with the disorder are more likely to be encountered in forensic settings, whereas women with the disorder are more likely to be found in psychiatric settings. This difference in presentation may reflect the reduced severity of the aggressive acts committed by women with IED. But, more recent data suggest that the male:female ratio is closer to 1:1 (Coccaro et al. 2005).

Comorbidity Patterns

In contrast to the more restrictive DSM-III and DSM-III-R criteria, the DSM-IV-TR definition of IED allows signs of generalized impulsivity or aggressiveness to be present between episodes. It also allows the psychiatrist to give an additional diagnosis of IED in the presence of another disorder if the episodes are not better accounted for by the other disorder. These changes were deemed necessary because the clinical reality is that most individuals who have intermittent episodes of aggressive behavior also have some impulsivity between episodes and often present with other past or current psychiatric disorders.

Subjects with IED most frequently have other Axis I and II disorders. The most frequent Axis I diagnoses comorbid with IED lifetime include mood, anxiety, substance, eating, and other ICDs ranging in frequency from 7% to 89% (Coccaro et al. 1998b, McElroy et al. 1998). Such Axis I comorbidity rates raise the question of whether IED constitutes a separate disorder. However, recent data finding earlier onset of IED compared with all disorders, except for phobic-type anxiety disorders, suggest that IED is not secondary to these other disorders (Coccaro et al. 2005).

McElroy et al. (1998) and McElroy (1999) studied 27 individuals who had symptoms that met criteria for IED and reported: “Twenty-five (93%) subjects had lifetime DSM-IV-TR diagnoses of mood disorders; 13 (48%), substance use disorders; 13 (48%), anxiety disorders; 6 (22%), eating disorders; and 12 (44%), an ICD other than IED. Subjects also displayed high rates of comorbid migraine headaches. First-degree relatives displayed high rates of mood, substance use, and impulse-control disorders.” McElroy et al. (1998) reported that the aggressive episodes observed in their subjects resembled “microdysphoric” manic episodes. Symptoms in common with both manic and IED episodes included irritability (79-92%), increased energy (83-96%), racing thoughts (62-67%), anxiety (21-42%), and depressed (dysphoric) mood (17-33%). However, this finding may not be surprising, because 56% of the subjects in question had a comorbid bipolar diagnosis of some type (bipolar I, 33%; bipolar II, 11%; and bipolar not otherwise specified or cyclothymia, 11%). The Rhode Island Hospital Study (Coccaro et al. 2005) suggests a much lower rate of comorbid bipolar illness, with a rate of 11% (bipolar I, 5%; bipolar II, 5%; and bipolar not otherwise specified, 1%). Regardless, clinicians should fully evaluate for bipolar disorder prior to determining treatment for IED, because mood stabilizers, rather than serotonin reuptake inhibitors (SSRIs), would be the first-line treatment for IED comorbid with bipolar disorder.

McElroy et al. (1998) reported that up to 44% of their IED subjects had another impulse-control–type disorder such as compulsive buying (37%) or kleptomania (19%). However, Coccaro et al. (1998b) found that IED subjects had a comorbid ICD, and only 5% of IED subjects had another ICD in the Rhode Island Hospital Study (Coccaro et al. 2005).

Some children with Tourette’s disorder may be prone to rage attacks (Budman et al. 1998, 2000). The clinical manifestation of these attacks is similar to IED and may be more common among children with Tourette’s who have comorbid mood disorders. On the basis of these observations, the rage attacks of these children may flow from an underlying dysregulation of brain function (Budman et al. 1998, 2000).

The limited literature on the comorbidity of impulsive aggressive episodes suggests that it often occurs with three classes of disorders:

1. Personality disorders, especially ASPD and BPD. By definition, ASPD and BPD are chronic and include impulsive aggression as an essential feature. Therefore, their diagnosis effectively excludes the diagnosis of IED (Figure 80–2). Coccaro et al. (1998b) reported the rate of BPD and/or ASPD in IED subjects to be 38%. However, rates of IED in subjects with BPD have been noted at 78% and in subjects with ASPD at 58% (Coccaro et al. 1998b). A review of unpublished data from the author’s lab (Hollander 2007) (Hollander E [2007], personal communication) suggests that these rates are
Aggressive behavior

Due to the direct effects of a general medical condition

- Yes: Associated with multiple cognitive deficits, including memory impairment
- No: Delirium due to a general medical condition

Due to the direct effects of a substance

- Yes: In excess of that usually encountered with intoxication or withdrawal
- No: Substance intoxication/substance withdrawal

In response to a delusion or hallucination

- Yes: Psychotic disorder (e.g., schizophrenia, mood disorder with psychotic features)
- No: Manic or mixed episode (in bipolar disorder, schizoaffective disorder)

Occurring in the context of elevated mood

- Yes: Major depressive episode in major depressive disorder or schizoaffective disorder
- No: Manic or mixed episode in major depressive disorder or schizoaffective disorder

Occurring in the context of depressed mood (e.g., murder of loved one preceding a suicide)

- Yes: Antisocial personality disorder
- No: Conduct disorder

Occurring as part of a pattern of antisocial behavior

- Yes: Borderline personality disorder
- No: Intermittent explosive disorder

Occurring as part of a pattern of intense anger with onset in early adulthood

- Yes: Acute stress disorder/posttraumatic stress disorder
- No: Adjustment disorder NOS

Episodes of aggressive behavior out of proportion to the situation

- Yes: Impulse control disorder NOS
- No: Criminal behavior

Associated with psychosocial stressor

- Yes: In response to an extreme stressor and accompanied by recurrent reexperiencing of the event
- No: Adjustment disorder NOS

Clinically significant impairment in impulse control not covered above

- Yes: Criminal behavior
- No: Adjustment disorder NOS

"Normal" aggressive behavior

Figure 80–2  Differential diagnosis of aggression. The psychiatric nosology of aggression has not been well worked out and requires much additional study. This is a particularly unfortunate state of affairs because the attribution (or misattribution) of aggression to a mental disorder is a frequent focus of forensic attention and can mean the difference between a life term in prison or a promotional tour for a bestseller. Because of the inherent difficulties in making these determinations, psychiatric testimony in this regard should be interpreted with caution. Other decision trees that may be of interest include those for catatonia; delusions; euphoria or irritability; disorganized, agitated, or unusual behavior; impulsivity; hallucinations; substance use; and general medical condition.

lower among subjects not seeking treatment and are lowest in the community (23% for BPD and/or ASPD; see also Coccaro et al. 2004). Regardless, BPD and ASPD subjects with a comorbid diagnosis of IED do appear to have higher scores for aggression and lower scores for general psychosocial function than do BPD/ASPD subjects without IED (Coccaro et al. 2005).

2. A history of substance use disorders, especially alcohol abuse. A concurrent diagnosis of substance intoxication excludes the diagnosis of IED. However, many patients with IED report past or family histories of substance abuse, and in particular alcohol abuse. In light of evidence linking personal and family history of alcohol abuse with impulsive aggression (Linnoila et al. 1989)
and linking both with low central serotonergic function (reviewed later), this connection may be clinically relevant. Thus, when there is evidence suggesting that alcohol abuse may be present, a systematic evaluation of IED is warranted, and vice versa.

3. Neurological disorders, especially severe head trauma, partial complex seizures, dementias, and inborn errors of metabolism. IED is not diagnosed if the aggressive episodes are a direct physiological consequence of a general medical condition. Such cases would be diagnosed as personality change due to a general medical condition, delirium, or dementia. However, individuals with IED often have nonspecific findings on neurological examination, such as reflex asymmetries, mild hand-eye coordination deficits, and childhood histories of head trauma with or without loss of consciousness. Their EEGs may show nonspecific changes. Such isolated findings are compatible with the diagnosis of IED and preempt the diagnosis only when they are indicative of a definitely diagnosable general medical or neurological condition. Such “soft” neurological signs may be diagnosed by a full neurological examination and neuropsychological testing.

Course
Given the rarity of pure IED, limited research is available concerning the age at onset and natural course of IED. But, according to the DSM-IV-TR (American Psychiatric Association 2000), and anecdotal case reports, the onset appears to be from childhood to the early 20s, and may be abrupt and without a prodromal period. The age of onset and course of IED distinguish it as separate from its comorbid diagnoses. The course of IED is variable, with an episodic course in some and a more chronic course in others. IED may persist well into middle life unless treated successfully. In some cases, it may decrease in severity or remit completely with old age. However, cognitive impairment caused by Alzheimer’s disease and other age-related causes of dementia may result in the reappearance of impulsive aggressive behavior. A mean age at onset of 16 years and an average duration of about 20 years has been described (McElroy et al. 1998).

Preliminary data (Coccaro et al. 2005) confirm these findings and indicate that onset of DSM-IV-TR IED occurs by the end of the first decade in 31%, by the end of the second decade in 44%, by the end of the third decade in 19%, and by the end of the fourth decade in only 6%. The mean age at onset in the NCS-R study was 14 years (Kessler et al. 2006).

Episodes typically last less than 30 minutes and involve one or a combination of physical assault, verbal assault, or destruction of property. If provoked, it is usually from a known person and is seemingly minor in nature (McElroy et al. 1998). Many individuals frequently have minor aggressive episodes in the interim between severely aggressive/destructive episodes. Considerable distress, social, financial, occupational, or legal impairments typically result from these episodes.

Differential Diagnosis
The differential diagnosis of IED covers the differential diagnosis of impulsivity and aggressive behavior in general. Aggression is defined as forceful physical or verbal action, which may be appropriate and self-protective or inappropriate as in hostile or destructive behavior. It may be directed against another person or the environment, or toward the self. The psychiatric nosology of aggression is still preliminary. Impulsivity is defined as the tendency to act in a sudden, unpremeditated, and excessively spontaneous fashion. The IED diagnosis should be considered only after all other disorders associated with impulsivity and aggression have been ruled out. Chronic impulsivity and aggression may occur as part of a cluster B personality disorder (e.g. BPD and ASPD); during the course of substance use disorders and substance intoxication; in the setting of a general medical (usually neurological) condition; and as part of disorders first diagnosed during childhood and adolescence such as conduct disorder, oppositional defiant disorder, ADHD, and mental retardation. In addition, impulsive aggression may appear during the course of a mood disorder, especially during a manic episode, which precludes the diagnosis of IED, and during the course of an agitated depressive episode. Impulsive aggression may also be an associated feature of schizophrenia, in which it may occur in response to hallucinations or delusions. Impulsive aggression may also appear in variants of obsessive-compulsive disorder (OCD), which may present with concurrent impulsive and compulsive symptoms.

A special problem in the differential diagnosis of impulsive aggression, which may arise in forensic settings, is that it may represent purposeful behavior, which is distinguished from IED by the presence of motivation and gain in the aggressive act, such as monetary gain, vengeance, or social dominance. Another diagnostic problem in forensic settings is malingering, in which individuals may claim to have IED to avoid legal responsibility for their acts. Figure 80–2 presents the differential diagnosis of aggression.

Common disorders that should be excluded before IED is diagnosed and features that may be helpful in the differential diagnosis are summarized in Table 80–1.

Differences in Gender and Cultural Presentations
Amok is an extremely rare culture-specific syndrome of episodic aggression first described in the Malay Peninsula but later found in Africa and Papua New Guinea. Amok is an episode of sudden, unprovoked rage in which the affected individual runs around with a weapon and attempts to kill a number of people or animals. Sometimes the perpetrator, typically a man, then kills himself. If captured alive, the individual with amok claims no memory of the acts. The etiology of amok and its relation to IED are unclear. Episodic violent behavior is more common in males than in females (DSM-IV-R).

Etiology and Pathophysiology
Theories about the etiology of impulsive aggressive outbursts and IED have been part of psychiatry from its origins. Possession by spirits, humoral imbalances, and “moral weakness” were all suggested to play a role. Since the second-half of the 19th century, two main lines of explanation, which are to a large extent complementary, have been developed to account for the existence of individuals with episodic impulsive aggression. One line of explanation viewed the etiology of impulsive aggression as stemming from the effects of early childhood experiences and possibly
childhood trauma on the development of self-control, frustration tolerance, planning ability, and gratification delay, which are all important for self-prevention of impulsive aggressive outbursts. Early experiences with “good-enough” mothering that fosters phase-appropriate delay of gratification and the development of the potential for imitation and identification with the mother are considered important for normal development. Too much or too little frustration, as well as overgratification or undergratification, may impair the normal development of the ability to anticipate frustration and delay gratification (Khantzian and Mack 1983).

A second line of explanation, which has yielded numerous positive findings over the past 15 years, views impulsive aggression as the result of variations in brain mechanisms that mediate behavioral arousal and behavioral inhibition. A rapidly growing body of evidence has shown that impulsive aggression may be related to defects in the brain serotonergic system, which acts as an inhibitor of motor activity (Kavoussi et al. 1997, Staner and Mendlewicz 1998). Animal studies suggest that serotonergic neurons play a role in behavioral inhibition and thus provide an impetus to explore the role of serotonin in human impulsivity. Although the majority of the human studies involved patients who suffered from impulsive aggression in the context of disorders other than IED, their findings may be relevant to the behavioral dimension of impulsive aggression, of which IED is a “pure” form.

Measures examining central (and peripheral) serotonin function correlate inversely with life history, questionnaire, and laboratory measures of aggression. This relationship has been demonstrated by CSF 5-HIAA (Linnoila et al. 1983, Virkkunen et al. 1994), physiological responses to serotonin agonist probes (Coccaro et al. 1989, 1997b, Dolan et al. 2001, Manuck et al. 1998), and platelet measures of serotonin activity (Birmaher et al. 1990, Coccaro et al. 1996). The type of aggression associated with reduced central serotonin function appears to be impulsive, as opposed to nonimpulsive, aggression (Linnoila et al. 1983, Virkkunen et al. 1994). Linnoila et al. (1989) divided aggressive behaviors into impulsive and nonimpulsive forms and found that reduced CSF 5-HIAA was correlated with impulsive aggression only. These findings suggest that impulsive aggressive behavior can be distinguished biologically from nonimpulsive aggression. Interestingly, the inverse relationship between aggression and serotonin is not observed when catecholamine system function is impaired (Coccaro et al. 1989, Wetterer et al. 1991). Siever et al. (1991) and Stein et al. (1993) have confirmed a relationship between levels of 5-HIAA in the CSF and impulsive or aggressive behaviors. Pharmacological challenge studies have also demonstrated that low serotonergic responsiveness (measured by the neuroendocrine response to serotonergic agonists) correlates with scores of impulsive aggression. Studies of impulsive aggression among alcoholics have further defined a probable relationship between such behaviors and diminished serotonergic function (Virkkunen et al. 1995, Virkkunen and Linnoila 1993).

There is also evidence to support the role of nonserotonergic brain systems and modulators in impulsive aggression. These findings suggest a role for dopamine (Depue et al. 1994), norepinephrine (Coccaro et al. 1991), vasopressin (Coccaro et al. 1998a), brain-derived neurotrophic factor (Lyons et al. 1991), opiates (Post et al. 1984), and testosterone one (Giammanco et al. 2005, Virkkunen et al. 1994) and an inhibitory interaction between neuronal nitric oxide synthase and testosterone in rodents (Kriegsfeld et al. 1997).

Another line of neurobiological evidence links impulsive aggression with dysfunction of the prefrontal cortex (PFC). Studies of neuropsychiatric patients with localized brain lesions have demonstrated that some bilateral lesions in the PFC may be specifically associated with a chronic pattern of impulsive aggressive behaviors. Neurological studies suggest that the PFC regions associated with impulsive aggression syndromes are involved in the processing of affective information and the inhibition of motor responsiveness, both of which are impaired in impulsive aggressive patients. Interictal episodes of aggression may occur among some people with epilepsy. In a quantitative MRI study of such episodes among people with temporal lobe epilepsy (TLE) (Woermann et al. 2000) three groups (24 TLE patients with aggressive behavior, 24 TLE patients without such behavior, and 35 nonpatient controls) were compared. The aggressive behavior was associated with a reduction of frontal neocortical gray matter.

Further evidence linking the PFC with the serotonergic system and impulsive aggression comes from postmortem and animal studies suggesting that the PFC is rich in excitatory 5-HT₂ receptors, whose number is increased in suicide victims and correlated with aggressive social behavior in primates. Lower levels of CSF 5-HIAA were found in neurological patients with frontal brain injuries than in patients with injuries in other brain regions. The fenfluramine challenge test, a neuroendocrine challenge to the serotonergic system, was found to increase cerebral prefrontal glucose metabolism in normal control subjects. PET studies have found selective reductions in glucose metabolism in the prefrontal and frontal cortex of patients with impulsive aggression. The regional reductions in glucose metabolism in impulsive aggressive patients were more significant during a continuous performance task, whose performance was impaired in neurological patients with frontal lesions and was found to increase frontal glucose metabolism in normal subjects (Raine et al. 1994). A visual-evoked potential and EEG study in a large group of aggressive children and adolescents also suggest that such behavior may be associated with altered innate characteristics of central nervous system function (Bars et al. 2001).

Thus, biological studies implicate the serotonergic system and the PFC in the pathogenesis of impulsive aggression. The diagnosis of IED is sometimes considered in forensic settings; the biological correlates of impulsive aggression focus attention on, but do not solve, the complicated problem of personal responsibility for impulsive violent acts that are correlated with objective biological findings.

**Family and Twin Studies**

Clinical observation and family history data suggest that IED is familial. Familial aggregation of temper outbursts and IED has been reported in psychiatric patients with “temper problems” (Mattes and Fink 1987). McElroy et al. (1998) reported that nearly a third of first-degree relatives of IED probands had IED. A blinded, controlled, family history study using IED-integrated research criteria (Coccaro 1999) found a morbid risk of IED of 26% in relatives of IED-IR probands compared with 8% among the relatives of control probands, a significant difference. Although twin studies have
confirmed the hypothesis that both impulsivity (Seroczynski et al. 1999) and aggression (Coccaro et al. 1997a) are under substantial genetic influence, there are no twin studies of IED itself. Genetic influence for these two traits ranges from 28% to 47%, with nonshared environmental influences making up the lion’s share of the remaining variance.

**Molecular Genetic Studies**

Studies of particular genes in aggressive populations have used the candidate gene approach. Candidate genes are the genes for proteins with a suspected, or proven, biological association to a disorder [e.g., serotonin (5-HT) receptors in aggression]. The polymorphism HTR1B/G861C and short tandem repeat locus D6S284 are part of the gene for the 5-HT1B receptor for serotonin. These genetic sites were examined in 350 Finnish sibling pairs and 305 Southwestern American Indian sibling pairs, both with a high rate of alcoholism. The diagnoses of ASPD and IED were used to examine the traits of impulsivity and aggression. The rate of IED in relatives of ASPD probands was 15%, and the relatives of healthy control subjects had neither IED nor ASPD. Lappalainen et al. (1998) were able to discover that the gene predisposing to ASPD alcoholism resides close to the HTR1B version of the coding sequence. They concluded that impulsivity and aggression might be influenced, in part, by 5-HT1B receptors. Other candidate genes include the genes for tryptophan hydroxylase and MAO-A. Manuck et al. (1999, 2000) found an association of the traits of aggression, impulsivity, and serotonin activity (tested by O,1fenfluramine challenge) with variations in both the tryptophan hydroxylase and the MAO-A genes in community samples.

**Imaging and Brain Localization**

Few localization and functional studies have looked at impulsive aggression or IED. Using fluorodeoxyglucose positron emission tomography (FDG-PET), Siever et al. (1999) found blunted glucose utilization responses to serotonin stimulation in the orbitofrontal cortex (an area associated with impulsive aggression) of IED subjects with BPD. A similar finding was reported in the anterior cingulate and anteromedial orbital cortex of impulsive aggressive subjects after stimulation with the direct serotonin agonist m-chlorophenylpiperazine (New et al. 2002). Using PET with a 5-HT1A antagonist in healthy volunteers, Parsey et al. (2002) found a significant inverse correlation between lifetime aggression and serotonin receptor binding in the dorsal raphe, anterior cingulate cortex, amygdala, medial PFC, and orbital PFC. Using neuropsychological testing in impulsive aggressive subjects, Best et al.'s (2002) data supported a possible dysfunctional frontal circuit. More work is needed to reveal the specific functional brain abnormalities in impulsive aggressive individuals.

**Treatment**

Given the rarity of pure IED, it is not surprising that few systematic data are available on its response to treatment and that some of the recommended treatment approaches to IED are based on treatment studies of impulsivity and aggression in the setting of other mental disorders and general medical conditions. Thus, no standard regimen for the treatment of IED can currently be recommended. Both psychological and somatic therapies have been utilized in the treatment of IED. A prerequisite for both modalities is the willingness of the individual to acknowledge some responsibility for the behavior and participate in attempts to control it.

**Psychological Treatment**

Lion (1992) has described the major psychotherapeutic task of teaching individuals with IED how to recognize their own feeling states and especially the affective state of rage. Lack of awareness of their own mounting anger is presumed to lead to the buildup of intolerable rage that is then discharged suddenly and inappropriately in a temper outburst. Patients with IED are therefore taught how to first recognize and then verbalize their anger appropriately. In addition, during the course of insight-oriented psychotherapy, they are encouraged to identify and express the fantasies surrounding their rage. Group psychotherapy for temper-prone patients has also been described. The cognitive-behavioral model of psychological treatment may be usefully applied to problems with anger and rage management.

Anger treatment studies focus on treatment of anger as a component of other psychiatric illnesses, like substance abuse, post-traumatic stress disorder, depression, and domestic violence; and in forensic and mentally impaired populations. In a few rare cases, anger is addressed as the primary or only problem, and a limited number of treatments have been described. “Imaginational exposure therapy,” used frequently in anxiety disorders, was studied in a noncontrolled pilot study of anger treatment (Grodnitzky and Tafrate 2000). Subjects habituated to anger-provoking scenarios, and the treatment was felt to be useful. In a controlled trial of high driving anger college students, Deffenbacher et al. (2000) compared pure relaxation training with relaxation training combined with cognitive therapy and an assessment-only control. Neither treatment condition improved general trait anger, but both treatments improved driving anger. When repeated in a new population of drivers with higher anger levels, both treatments lowered trait anger (Deffenbacher et al. 2002). Since relaxation training with cognitive therapy provided little gain over pure relaxation training, relaxation training in itself may be adequate treatment for driving anger.

Other versions of cognitive-behavioral therapy (CBT), like dialectical behavior therapy (DBT), have been studied in BPD patients. One study showed improvement in anger, global functioning, and social adjustment compared with a treatment-as-usual condition (Linehan et al. 1994). Improvement in anger and impulsivity has been shown with DBT across many disorders. There are no published double-blind, placebo-controlled studies on IED subjects in therapy, but studies of therapy in IED subjects are ongoing.

**Somatic Treatments**

Several classes of medications have been used to treat IED and impulsive aggression in the context of other disorders. These included beta-blockers (propranolol and metoprolol), anticonvulsants (carbamazepine and valproic acid), lithium, antidepressants (tricyclic antidepressants and SSRIs), and antianxiety agents (lorazepam, alprazolam, and buspirone). Mattes (1990) compared the effectiveness of two commonly used agents, carbamazepine and propranolol, for the treatment of rage outbursts in a heterogeneous group of patients. He found that although carbamazepine and propranolol were overall equally effective, carbamazepine was
Clinical Vignette 1

Mr. A is a 42-year-old separated man who works as a bank clerk. He came to seek outpatient psychiatric treatment after an angry outburst that led to the breakdown of his second marriage: his wife issued an order of protection against him after a rage attack in which he slapped her across the face and destroyed most of the kitchen and living room furniture. His rage was triggered by his wife’s decision to buy a new microwave oven without consulting him. Mr. A, who remembered the episode clearly and with remorse, said that he realized how angry he was only after he actually struck at his wife.

During the course of his evaluation, Mr. A became tearful and admitted to several similar episodes during the course of his current and previous marriages. These episodes were rare, occurring once or twice a year. They were brief and apparently unpredictable and resulted in his separation from his first wife. Except during those episodes, Mr. A was a pleasant, rather timid man who deferred to his wife in most important decisions. There was no history suggestive of antisocial or borderline personality disorder. Mr. A, who described himself as a shy, withdrawn child, gave a history of head trauma at the age of 12 years, while he was ice skating, with loss of consciousness for 10 minutes. Other than this, his medical history was normal.

There were no neurological or behavioral sequelae. Mr. A also described prolonged physical abuse by his alcoholic father. Mr. A himself denied a history of substance abuse, involvement with the criminal justice system, and prior psychiatric treatment. He denied a history of manic and depressive episodes. Mr. A had few friends and was not popular at his job. Although he had never lost his temper there, he believed that his boss and coworkers could sense his “stress” while dealing with clients.

Mr. A’s physical and neurological examination was notable only for mild bilateral difficulty with rapid alternating hand movements. Except for his tearfulness while describing the episode, Mr. A’s Mental Status Examination was unremarkable. Results of routine laboratory blood work and computed tomography of the head were within normal limits. An EEG was notable for diffuse slowing without an epileptic focus.

Mr. A’s treatment was started with carbamazepine at standard dosage. He also received a short course of psychotherapy that focused on recognizing his anger and venting it appropriately, on his memories of childhood physical abuse, and on his current sense of himself as a helpless person who was being controlled by his wife and boss. In addition, it was recommended that he transfer to a position that would not involve contact with clients. During a 2-year follow-up, Mr. A had no further rage episodes. He continued to have few friends but was able to maintain a long-term relationship with a woman he was planning to marry.
childhood and poor parenting, and in addition acute stressors may be present, such as marital or sexual conflicts. The patient experiences the urge to steal as irresistible, and the thefts are commonly associated with a thrill, a high, a sense of relief, or gratification. Generally, the behavior has been hard to control and has often gone undetected by others. The kleptomania may be restricted to specific settings or types of objects, and the patient may or may not be able to describe rationales for these preferences. Quite often, the objects taken are of inherently little financial value, or have meaningless financial value relative to the income of the person who has taken the object. Additionally, the object may never actually be used. These factors often help distinguish criminal theft from kleptomania. The theft is followed by feelings of guilt or shame and, sometimes, attempts at atonement. The frequency of stealing episodes may greatly fluctuate in concordance with the degree of depression, anxiety, or stress. There may be periods of complete abstinence. The patient may have a past history of psychiatric treatments including hospitalizations or of arrests and convictions, whose impact on future kleptomanic behavior can be variable.

**DSM-IV-TR Criteria**

Kleptomania

A. Recurrent failure to resist impulses to steal objects that are not needed for personal use or for their monetary value.

B. Increasing sense of tension immediately before committing the theft.

C. Pleasure, gratification, or relief at the time of committing the theft.

D. The stealing is not committed to express anger or vengeance and is not in response to a delusion or a hallucination.

E. The stealing is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder.

F. The stealing is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder.

Epidemiology

No epidemiological studies of kleptomania have been conducted, and thus its prevalence can be estimated only grossly and indirectly. In a thorough review of the existing literature, Goldman (1991) found that in a series of shoplifters, the estimate of kleptomania ranged from 0% to 24%. The frequency of kleptomania may be indirectly extrapolated from incidence rates of kleptomania in comorbid disorders with known prevalence, like bulimia nervosa. Such speculations suggest at least a 0.6% prevalence of kleptomania in the general population (Goldman 1991). However, given that people who shoplift are often not caught, this is almost certainly an underestimate. Also, the shame and embarrassment associated with stealing prevents most people from voluntarily reporting kleptomania symptoms (Grant and Kimm 2002c). In addition, studies examining comorbidity of other disorders may neglect to inquire about kleptomania. Studies of kleptomania in various clinical samples suggest a higher prevalence. A recent study of 204 adult psychiatric inpatients in the US, with multiple disorders, revealed that kleptomania may in fact be fairly common. The study found that 7.8% (n = 16) endorsed current symptoms consistent with a diagnosis of kleptomania and 9.3% (n = 19) had a lifetime diagnosis of kleptomania (Grant et al. 2005). Kleptomania appeared equally common in patients with mood, anxiety, substance use, or psychotic disorders. These findings are further supported by two French studies. One study of 107 depressed inpatients found that 4 (3.7%) had kleptomania (Lejoeux et al. 2002); in another study of 79 alcohol-dependent inpatients, 3 (3.8%) reported symptoms consistent with kleptomania (Lejoeux et al. 1999). In two studies examining comorbidity in pathological gamblers, rates of comorbid kleptomania ranged from 2.1% to 5% (Grant and...

The literature clearly suggests that the majority of patients with kleptomania are women (e.g. Grant and Kim 2002b, McElroy et al. 1991b, Presta et al. 2002). In a retrospective review of 56 cases that appeared to fulfill DSM-III-R criteria for kleptomania, McElroy et al. (1991b) found that 77% were women. Similarly, in a prospective series of 20 patients with DSM-III-R kleptomania, 75% were women (McElroy et al. 1991a). However, women generally seek psychiatric help more frequently than men, whereas men are more likely to become involved with the penal system (Goldman 1991). Consequently, this may not reflect true gender distribution. The severity of kleptomania symptoms and the clinical presentation of symptoms do not appear to differ based on gender (Grant and Kim 2002b).

Comorbidity Patterns
High rates of other psychiatric disorders found in patients with kleptomania have sparked debate over the proper characterization of this disorder. Among those with kleptomania who present for treatment, there is a high incidence of comorbid mood, anxiety, and eating disorders, when compared with rates in the general population. Rates of lifetime comorbid affective disorders range from 59% (Grant and Kim 2002b) to 100% (McElroy et al. 1991b). The rate of lifetime comorbid bipolar disorder has been reported as ranging from 9% (Grant and Kim 2002b) to 27% (Bayle et al. 2003) to 60% (McElroy et al. 1991b). Studies have also found high lifetime rates of comorbid anxiety disorders (60–80%; McElroy et al. 1991b, 1992), ICDs (20–46%; Grant and Kim 2003), substance use disorders (23–50%; Grant and Kim 2002b, McElroy et al. 1991b), and eating disorders (60%; McElroy et al. 1991b). Personality disorders have been found in 43–55% of kleptomania patients, the most common being paranoid and histrionic personality disorder (Bayle et al. 2003, Grant 2004).

In reviewing 26 case reports of kleptomania, Goldman (1991) reported mention of histories of depression in 13 patients (50%), anxiety in 8 patients (31%), and bulimia nervosa in 3 patients (12%). Similar percentages are noted by McElroy et al. (1991b) in a review of 56 patients with probable kleptomania: 57% with mood disorder symptoms, 34% with anxiety disorder symptoms, and 11% with bulimic symptoms. Comorbidity patterns among those who present for treatment may be greater than among random samples. More reliable comorbidity rates can be found in a prospective study of 20 kleptomaniacs (McElroy et al. 1991a). Lifetime DSM-III-R comorbidity rates were 40% major depressive disorder, 50% substance abuse, 40% panic disorder, 40% social phobia, 45% OCD, 30% anorexia nervosa, 60% bulimia nervosa, and 40% other ICDs. Dissociative symptoms, significant character pathology, and trauma histories are commonly encountered among this group (Goldman 1991, McElroy et al. 1991b). Unfortunately, Axis I dissociative pathology and Axis II pathology have not yet been systematically investigated in these patients.

Course
Kleptomania may begin in childhood, adolescence, or adulthood, and sometimes in late adulthood. However, most patients have an onset of symptoms before the age of 21 years, that is, by late adolescence (Goldman 1991, Grant and Kim 2002b, McElroy et al. 1991a, 1991b; Presta et al. 2002). In two separate studies, the mean age at onset was 20 years (Goldman 1991, McElroy et al. 1991a, 1991b) and in some cases 15 or 16 years may elapse before treatment is sought (Goldman 1991, McElroy et al. 1991a).

The disorder appears to be chronic, but with varying intensity. At peak frequency, McElroy et al. (1991a) found a mean of 27 episodes a month, essentially daily stealing, with one patient reporting four acts daily. The majority of patients may eventually be apprehended for stealing once or more, and a minority may even be imprisoned; usually these repercussions do not result in more than a temporary remission of the behavior. People with kleptomania may also have extensive histories of psychiatric treatments, including hospitalization for other conditions, most commonly depression or eating disorders. Because of the unavailability of longitudinal studies, the prognosis is unknown. However, it appears that without treatment the behavior may be likely to persist for decades, sometimes with significant associated morbidity, despite multiple convictions for shoplifting (arrest or imprisonment), with transient periods of remission. Three typical courses have been described: sporadic with brief episodes and long periods of remission; epidemic with protracted periods of stealing and periods of remission; and chronic with varying intensity (DSM-IV-TR, American Psychiatric Association 2000).

Etiology and Pathophysiology
The etiology of kleptomania is essentially unknown, although various models have been proposed in an effort to conceptualize the disorder. At present, the available empirical data are insufficient to substantiate any of these models. With the exception of scant information on family history, data regarding possible familial or genetic transmission of a kleptomania diathesis are unavailable. One study found the risk for major mood disorders in first-degree relatives of probands with kleptomania to be 0.31; similar to the familial risk for probands with major depressive disorder (McElroy et al. 1991a). In the same study, 7% of first-degree relatives of kleptomania patients had histories of OCD. These findings, along with other lines of evidence, suggest that kleptomania shares a common biological diathesis with mood disorders or OCD. The affective spectrum model suggests that kleptomania and other ICDs may share a common underlying biological diathesis with other disorders like depression, panic disorder, OCD, and bulimia nervosa (McElroy et al. 1992, 1991b, Hudson and Pope 1990). The apparent high comorbidity of kleptomania with depression and bulimia nervosa has already been noted. As early as 1911, Janet (1911) recognized the alleviation of depressive symptoms on the commission of kleptomanic acts. Some individuals with kleptomania respond to treatment with thymoleptic agents or electroconvulsive therapy. These observations are cited as support for an affective spectrum model.
Although the affective spectrum has been claimed to encompass obsessive-compulsive pathology (Hudson and Pope 1990) there exists a more specific model conceptualizing kleptomania and other impulse disorders as obsessive-compulsive spectrum disorders (McElroy et al. 1993). Several lines of evidence support this model. First, there are phenomenological similarities between the classical obsessions and compulsions of OCD and the irresistible impulses and repetitive actions characteristic of kleptomania. Further, there appears to be a greater than chance occurrence of OCD in probands with kleptomania and in their relatives. In addition, both conditions have significant comorbidity with mood, anxiety, substance use, and eating disorders. However, OCD rituals are more clearly associated with relief of anxiety and harm avoidance, whereas kleptomania acts seem to be associated with gratification or pleasure. In addition, OCD is associated with a clear preferential response to SSRIs as opposed to general thymoleptics. The limited treatment literature (see later) does not support a similar response pattern in kleptomania. Unfortunately, the role of the serotonergic or of any other neurotransmitter system has not been sufficiently investigated in kleptomania. Interestingly, a large study found subjects with mixed anorexia and bulimia nervosa to have a higher lifetime prevalence of kleptomania than those with either anorexia or bulimia nervosa alone (Herzog et al. 1992). This could suggest a relationship between kleptomania and both the obsessive-compulsive (anorexic) and the affective (bulimic) spectrum.

Alternatively, kleptomania may be conceptualized as an addictive disorder. The irresistible impulse to steal is reminiscent of the urge and highly associated with drinking or drug use (McElroy et al. 1992). Marks (1990) proposed a constellation of behavioral (i.e., nonchemical) addictions encompassing OCD, compulsive spending, gambling, binging, hypersexuality, and kleptomania. This model postulates certain concepts thought to be common in all these disorders, like craving, mounting tension, “quick fixing,” withdrawal, external cuing, and habituation. These components have not yet been well investigated in kleptomania.

**Biological Theories**

**Serotonin and Inhibition**

Compared with controls, kleptomania patients report significant elevations of impulsivity and risk taking (Bayle et al. 2003; Grant and Kim 2002d), and diminished inhibitory mechanisms may underlie the risk-taking behavior of kleptomania. The most well-studied inhibitory pathways involve serotonin and the PFC (Chambers et al. 2003). Decreased measures of serotonin have long been associated with a variety of adult risk-taking behaviors including alcoholism, fire setting, and pathological gambling (Moreno et al. 1991; Virkkunen et al. 1994). Blunted serotonergic responses in the ventromedial PFC have been seen in people with impulsive aggression (New et al. 2002), and this region has also been implicated in poor decision making (Bechara 2003), as seen in those with kleptomania. Although there are few biological studies of kleptomania, early evidence supports a theory of serotonergic involvement in the disorder. One study found a lower number of the platelet serotonin transporter in kleptomania patients versus healthy controls (Marazziti et al. 2000). Pharmacological case studies suggest that SSRIs like clomipramine and SSRIs (Lepkifker et al. 1999, McElroy et al. 1991b) may reduce the impulsive behavior associated with kleptomania.

**Dopamine and Reward Deficiency**

Dopaminergic systems influencing rewarding and reinforcing behaviors have also been implicated in ICDs and may play a role in the pathogenesis of kleptomania. One proposed mechanism is “Reward deficiency syndrome,” a hypothesized hypodopaminergic state involving multiple genes and environmental stimuli that puts an individual at high risk for multiple addictive impulsive and compulsive behaviors (Blum et al. 2000). Alterations in dopaminergic pathways have been proposed as underlying the seeking of rewards (e.g., shoplifting) that trigger the release of dopamine and produce feelings of pleasure (Blum et al. 2000). Further, dopamine release into the nucleus accumbens has been implicated in the translation of motivated drive into action, serving as a “go” signal (Chambers et al. 2003). Dopamine release into the nucleus accumbens seems maximal when reward probability is most uncertain, suggesting that it plays a central role in guiding behavior during risk-taking situations (Fiorillo et al. 2003). The structure and function of dopamine neurons within the nucleus accumbens, in conjunction with glutamatergic afferent and intrinsic GABAergic activities, appear to change in response to experiences that influence the function of the nucleus accumbens. So, future behavior may be determined in part by prior rewarding experiences via neuroplastic changes in the nucleus accumbens. This may explain why, over time, many kleptomania patients report shoplifting “out of habit” even without a pronounced urge or craving.

**Opioid System, Cravings, and Pleasure**

Kleptomaniacs report frequent urges to steal, that result in theft twice weekly on average (Grant and Kim 2002b). Thus, urges linked to the experience of reward and pleasure may represent an important clinical target for treatment. Many indicate that the act of stealing reduces the urges or the tension these urges produce (McElroy et al. 1991b). While many report the urges as intrusive, the act of stealing is often a “thrill” for some, producing a pleasurable feeling (Goldman 1991, Grant and Kim 2002b). The μ-opioid system is thought to underlie urge regulation by processing reward, pleasure, and pain, in part through modulation of dopamine neurons in the mesolimbic pathway via γ-aminobutyric acid interneurons (Potenza and Hollander 2002). Studies of naltrexone, a μ-opioid antagonist, have shown its efficacy in reducing urges in those with kleptomania and other ICDs (Dannon et al. 1999, Grant and Kim 2002c, Kim et al. 2001).

In sum, repeated kleptomanic behavior may be a result of an imbalance between a pathologically increased urge and a pathologically decreased inhibition. The repeated shoplifting may therefore be due to increased activity of the mesocorticolimbic dopamine circuitry, indirectly enhanced through the opioid system, and decreased activity in the cortical inhibitor processes, largely influenced via serotonin.

Numerous psychological formulations of kleptomania have also been postulated over the years. A frequent theme reported by many authors and reviewed by Goldman (1991) and McElroy et al. (1991b) is that of kleptomania as an acting-out aimed at alleviating depressive symptoms. Fishbain
(1987) carefully described the case of a woman whose kleptomanic episodes were closely related to depressive bouts and who experienced an apparent antidepressant effect from the thrill and excitement of her risk-taking behavior. So kleptomania may result from an attempt to relieve feelings of depression through stimulation (Goldman 1991, McElroy et al. 1991a) and risk-taking behavior may produce an antidepressant effect for some patients (Fishbain 1987, Goldman 1991). Shoplifting may distract depressed patients from stressors and unpleasant cognitions. Ironically, problems resulting directly from shoplifting (e.g., embarrassment and shame from getting caught) may in turn lead to even more shoplifting as a misguided attempt of symptom management (Goldman 1991). Supporting the self-medication hypothesis of shoplifting, patients with kleptomania report high lifetime rates of depression (45-100%; Bayle et al. 2003, McElroy et al. 1991b) that usually (60% of cases) precedes the kleptomanic behavior (McElroy et al. 1991b). Further, several case studies report patients who described shoplifting as relief for their depressed moods (Fishbain 1987) and suggest that kleptomania symptoms improve with antidepressants (Lepkifker et al. 1999, McElroy et al. 1991b).

From a psychodynamic point of view, kleptomania has been viewed over the decades as a manifestation of a variety of unconscious conflicts, with sexual conflicts figuring prominently in the literature. Case reports have described conscious sexual gratification, sometimes accompanied by frank masturbation or orgasm during kleptomanic acts (Fishbain 1987, Fenichel 1945). Thus, it has been suggested that kleptomanic behavior serves to discharge a sexual drive that may have forbidden connotations similar to those of masturbation, and the stolen object itself may have unconscious symbolic or overt fetishistic significance. Although no systematic studies exist, there has long been an implication in the literature on kleptomania that those afflicted with kleptomania suffer disproportionately from a variety of sexual dysfunctions. Turnbull (1987) described six patients with a primary diagnosis of kleptomania, all of whom had dysfunctional sexual relationships with their partners, compulsive promiscuity, or anorgasmia.

Other cases of kleptomania have been understood as reflecting conflictual infantile needs and attempts at oral gratification, masochistic wishes to be caught and punished related to a harsh guilt-inducing superego or primitive aggressive strivings, penis envy or castration anxiety with the stolen object representing a penis, a defense against unwelcome passive homosexual longings, restitution of the self in the presence of narcissistic injuries, or the acquisition of transitional objects (Beldoch 1991). These various formulations are presented in detail in Goldman's review (1991). Psychodynamic interpretations associated with kleptomania should be carefully tailored to the individual. The literature on kleptomania has frequently implicated disturbed childhoods, inadequate parenting, and significant character disturbances in kleptomanic patients. From this perspective kleptomania can be more effectively understood in the context of an individual's overall character. Unfortunately, no clinical studies exist that systematically explore Axis II psychopathology in these patients.

Behavioral models also provide clues as to the pathogenesis of kleptomania. From an operant viewpoint, the positive reinforcer in kleptomania is the acquisition of items for nothing, and the intermittent reinforcement (e.g., not always being able to shoplift because of store security) of kleptomanic behavior may therefore be particularly resistant to extinction. Physiological arousal related to shoplifting (Goldman 1991) may be another reinforcer that initiates and perpetuates the behavior. Negative reinforcement (i.e., the removal of a punishing stimulus) hypothesizes that shoplifting is performed to experience relief from the aversive arousal of urges. The self-medication theory of kleptomania may represent a negative reinforcement. This could explain why kleptomaniac behavior continues despite the offender being frequently apprehended.

There may also be specific cognitive errors that are directly linked to kleptomanic behavior: (1) believing that only shoplifting will reduce the urge or the depressive state, (2) selective memory (e.g., remembering the thrill of shoplifting and ignoring the shame and embarrassment from being apprehended), and (3) erroneous self-assessment (e.g., that one deserves to be caught stealing because one is not intrinsically worth anything). A biopsychological perspective will most likely provide the most useful understanding for the treatment and prevention of kleptomania.

Treatment

Treatment Goals
The general goal of treatment is the eradication of kleptomanic behavior. Treatment typically occurs in the outpatient setting, unless comorbid conditions like severe depression, eating disturbances, or more dangerous impulsive behaviors dictate hospitalization. In the initial contact with the psychiatrist, as described earlier, it is important that the appropriate differential diagnoses be considered. The interview must be conducted in a respectful climate that ensures confidentiality. Patients may not only experience considerable guilt or shame for stealing, but also may be unrevealing because of the fear of legal repercussions. In the acute treatment phase, the aim is to decrease significantly or, ideally, eradicate episodes of stealing during a period of weeks to months. Concurrent conditions may compound the problem and require independently targeted treatment.

The acute treatment of kleptomania has not been, to date, systematically investigated. Recommendations are based on retrospective reviews, case reports, and small case series. Maintenance treatment for kleptomania has not been investigated either, and only anecdotal data exist for patients who have been followed up for significant periods after initial remission.

Psychiatrist-Patient Relationship
As with any condition that may be associated with intense guilt or shame, kleptomania must be approached respectfully by the psychiatrist. Patients can be reassured and their negative feelings alleviated to some degree with proper initial psychoeducation. The treatment alliance can be strengthened by consistently maintaining a nonjudgmental and supportive stance. In addition, patients' fears regarding breaks of confidentiality and criminal repercussions must be addressed.

No treatments have been systematically shown to be effective for kleptomania. These treatment recommendations are supported by case reports and retrospective reviews.
only. In general, it appears that thymoleptic medications and behavioral therapy may be the most efficacious treatments for the short term, while long-term psychodynamic psychotherapy may be indicated and have good results for selected patients.

**Somatic Treatments**

No medication is currently approved by the US Food and Drug Administration for treating kleptomania. So, it is important to inform patients of “off-label” uses of medications for this disorder and the empirical basis for considering medication treatment.

Various medications—tricyclic antidepressants, SSRIs (Lepkițker et al. 1999), mood stabilizers, and opioid antagonists—have been examined for the treatment of kleptomania (Grant and Kim 2002c, McElroy et al. 1989) with mixed results. In a literature review of 56 kleptomania cases, McElroy et al. (1991a) noted that somatic treatments were described for 8 patients. Significant improvement was reported for seven of these. Treatment included antidepressants alone, antidepressants with antipsychotics or stimulants, electroconvulsive therapy alone, or electroconvulsive therapy with antidepressants. The medications most commonly used to treat kleptomania are the antidepressants. In a series of 20 patients fulfilling DSM-III-R criteria for kleptomania, McElroy et al. (1991b) found that 18 had received antidepressants and of those patients 10 had partial or complete remission of both kleptomanic urges and behavior. It has been suspected that kleptomania may respond selectively to SSRIs because of the anticomulsive and anti-impulsive properties of these compounds. Of these 18 patients, 10 were administered fluoxetine alone and only 2 had a full response and 1 had a partial response. These data are not suggestive of a high response rate to SSRIs, but dose and duration of treatment were not explicitly stated. In a report on three patients with concurrent DSM-III-R kleptomania and bulimia nervosa treated with serotonergic antidepressants, two received high-dose fluoxetine and one trazodone; all three showed significant improvement in kleptomania, independent of the course of bulimia nervosa and depression (McElroy et al. 1989). It is still unclear whether kleptomania responds preferentially to serotonergic antidepressants, and this question awaits further study. Other agents reported to have treated kleptomania successfully include nortriptyline (McElroy et al.1991b) and amitriptyline (Fishbain 1987). So, although little is known about maintenance pharmacological treatment for kleptomania, the literature suggests that symptoms tend to recur with cessation of thymoleptic treatment and again remit when treatment is re instituted (McElroy et al.1991a, Fishbain 1987). But it remains unclear if the antikleptomanic effect of thymoleptics is dependent on or independent of their antidepressant effect.

A number of other medications have been employed to treat kleptomania. These include antipsychotics (McElroy et al.1991b, Fishbain 1987), stimulants (McElroy et al. 1991b), valproic acid (McElroy et al. 1991a), carbamazepine (McElroy et al. 1991a), clonazepam (McElroy et al. 1991a) and lithium (McElroy et al. 1991a, Monopolis and Lion 1983). Lithium augmentation may be of benefit when kleptomania does not respond to an antidepressant alone (Burstein 1992). Other agents used successfully as monotherapy for kleptomania include fluvoxamine (Chong and Low 1996) and paroxetine (Kraus 1999). Combinations of medications have also been effective in case reports: lithium plus fluoxetine (Burstein 1992), fluvoxamine plus buspirone (Durst et al. 1997), fluoxetine plus lithium, fluoxetine plus imipramine (McElroy et al. 1991b), and fluvoxamine plus valproate (Kmetz et al. 1997). Finally, there have been some reports of successful treatment of kleptomania with electroconvulsive therapy, which may have been administered for a concurrent mood disorder (McElroy et al. 1991b).

The findings from case reports have not been consistent. Seven cases of fluoxetine, three of imipramine, two of lithium as monotherapy, two of lithium augmentation, four of tranylcypromine, and one of carbamazepine combined with clomipramine all failed to reduce kleptomania symptoms (McElroy et al. 1991b). Some evidence suggests that SSRIs may even induce kleptomania symptoms (Kindler et al. 1997). A case series found that kleptomania symptoms respond to topiramate (Dannon 2003). In another case series, the two subjects treated with naltrexone responded (Dannon et al. 1999).

In the only open-label trial for kleptomania, naltrexone resulted in a significant decline in the intensity of urges to steal, stealing thoughts, and stealing behavior (Grant and Kim 2002c) (mean effective dosage 145 mg/day). A lower dosage, possibly 50 mg/day, may be effective in younger people with kleptomania (Grant and Kim 2002a). Opioid antagonists like naltrexone may be effective in reducing both the urges to shoplift and shoplifting behavior, by reducing the “thrill” associated with shoplifting and thus preventing the positive reinforcement of the behavior. Antidepressants, particularly those that influence serotonergic systems (e.g., SSRIs), may also be effective in reducing the symptoms of kleptomania, by targeting serotonergic systems implicated in impaired impulse regulation. If kleptomania represents both impaired urge regulation and inhibition of behavior, both opioid antagonists and antidepressants may play a role in controlling this behavior.

**Psychosocial Treatments**

Formal studies of psychosocial interventions for kleptomania have not been performed. However, a number of clinical reports have supported behavioral therapy for kleptomania. Different behavioral techniques have been employed with some success, including aversive conditioning, systematic desensitization, covert sensitization, and behavior modification. In their review of 56 cases of kleptomania, McElroy et al. (1991a) noted that the 8 patients who were treated with behavioral therapy—mostly aversive conditioning—showed significant improvement. We give here some specific examples of behavioral techniques that have been successfully employed and described. One patient was taught to hold her breath as a negative reinforcer whenever she experienced an impulse to steal (Keutzer 1972). Another patient was taught to use systematic desensitization techniques to control the mounting anxiety associated with the impulse to steal (Marzagao 1972). A patient treated by covert sensitization learned to associate images of nausea and vomiting with the desire to steal (Glover 1985). A woman who experienced sexual excitement associated with shoplifting and would masturbate at the site of the act was instructed to practice masturbation at home, while fantasizing kleptomanic acts (Fishbain 1987). The literature suggests that these techniques
remain effective over the long term (Gauthier and Pellerin 1982, Givan 1985). In imaginal desensitization, the patient imagines the steps of stealing and her ability to not steal in that context, while maintaining a relaxed state. Undergoing fourteen 15-minute sessions over 5 days, two patients reported complete remission of symptoms for a 2-year period (McConaghy and Blaszczynski 1988). Learning to substitute alternative sources of satisfaction and excitement when urges to steal occur has been successful in a woman treated weekly for 5 months, who reported 2 years of remitted symptoms (Gudjonsson 1987).

It appears that the most effective behavioral treatment of all may be complete abstinence, that is, the patient should no longer visit any of the stores or settings where kleptomanic acts occur. A number of patients who never come to psychiatric attention apparently employ this technique successfully, and it may be an appropriate treatment goal if it does not result in excessive restrictions of activity and lifestyle.

The clinical literature suggests that for most patients, behavioral therapy may be a more efficacious approach than insight-oriented psychotherapy. Insight-oriented psychotherapy, however, has been unsuccessful in treating this disorder in 11 published cases (McElroy et al. 1991b). Psychoanalysis has resulted in some limited success for kleptomania symptoms, but usually with the addition of medication (Fishbain 1988, Schwartz 1992). The psychodynamic treatment of kleptomania centers on the exploration and working through of the underlying conflict or conflicts. In a review of 26 case reports, McElroy et al. (1991a) reported that 4 of 5 patients had a good response to psychoanalysis or related therapy. However, in another review of 20 cases (meeting DSM-III-R criteria) McElroy et al. (1991b) reported that of 11 patients treated with psychotherapy, none showed improvement. There are case reports in the literature of successful psychodynamic treatment of kleptomania (Schwartz 1992). Such treatment, possibly in combination with other approaches, may be indicated for patients for whom a clear conflictual basis for the behavior can be formulated, who also have the needed insight and motivation to undertake this type of treatment. In proposing such treatments, which may be long term, the psychiatrist should consider whether there are immediate risks that must be addressed, such as a high risk of legal consequences.

As few empirical studies are available, research is needed to guide the selection of which psychotherapy to use, and to investigate of the combination of medication and psychotherapy in treating kleptomania.

Special Treatment Considerations

Little is known about treating kleptomania and therefore special treatment considerations have not been elucidated. However, it is clear that comorbid conditions, like depression, bulimia nervosa, OCD, or substance abuse, must be addressed along with the kleptomania. In addition to the inherent suffering and morbidity of these other disorders, their course and severity could compound the kleptomanic behavior. In the rare cases of a precipitating or exacerbating organic etiology, the underlying organic cause must be treated. In addition, the treatment of particular groups such as children or the elderly should take into account special contributing life stage or situational factors. The involvement of family or others on whom the patient is dependent may be indicated.

Refractoriness to Initial Treatment

There has not been sufficient study of the treatment of kleptomania to systematically delineate approaches to the refractory patient. However, general clinical principles can be applied. Medication trials should be maximized, predominately employing antidepressants and mood stabilizers, alone or in combination. In addition, it is important that comorbid conditions such as depression or OCD be monitored and treated, because they complicate the course of kleptomania. For patients who have no response or a partial response to pharmacotherapy alone or who do not want medication treatment, behavioral therapy is indicated. Behavioral therapy can be used alone or in combination with medication. There are no systematic comparisons of medication, behavioral therapy, or combined treatments. Therefore, the initial treatment choice is based in the assessment of the particular circumstances of each presentation. The patient's past treatment history, comorbid diagnoses, and personal resources should be weighed in choosing a course of treatment. Finally, there may be refractory patients for whom a multiple combination approach is helpful. Fishbain (1987) described the treatment of a middle-aged woman with a long history of kleptomania, depression, and suicidality and extensive past psychiatric treatments who responded to a combination of supportive and insight-oriented therapy, medication, and behavior modification.

Pyromania and Fire Setting Behavior

Diagnosis

Definition and Diagnostic Features

The primary characteristics of pyromania are recurrent, deliberate fire setting, the experience of tension or affective arousal before the fire setting, an attraction or fascination with fire and its contexts, and a feeling of gratification or relief associated with the fire setting or its aftermath. True pyromania is present in only a small subset of fire setters. Prins et al. (1985) have suggested the following motivations for intentional arson: financial reward, to conceal another crime, for political purposes, as a means of revenge, as a symptom of other (nonpyromania) psychiatric conditions (e.g., in response to a delusional belief), as attention-seeking behavior, as a means of deriving sexual satisfaction, and as an act of curiosity when committed by children. Revenge and anger appear to be the most common motivations for fire setting (O’Sullivan and Kelleher 1987). Fire setting may also be associated with other psychiatric diagnoses (see differential diagnosis section). Fire-setting behavior may be a focus of clinical attention, even when criteria for pyromania are not present. Because the large majority of fire-setting events are not associated with true pyromania (which is rare), this section also addresses fire-setting behavior in general. Recent diagnostic classifications include pyromania among the ICDs and fire setting is thought to result from a failure to resist an impulse. Although pyromaniacs may methodically prepare the fire and leave obvious clues of this preparation behind (Wise and Tierney 1999), pyromania is still considered an uncontrolled and often impulsive behavior.

The diagnosis of pyromania emphasizes the affective arousal, thrill, or tension preceding the act, as well as the feeling of tension relief or pleasure in witnessing the
Pyromania

A. Deliberate and purposeful fire-setting on more than one occasion.
B. Tension or affective arousal before the act.
C. Fascination with, interest in, curiosity about, or attraction to fire and its situational contexts (e.g., paraphernalia, uses, consequences).
D. Pleasure, gratification, or relief when setting fires, or when witnessing or participating in their aftermath.
E. The fire-setting is not done for monetary gain, as an expression of sociopathic ideology, to conceal criminal activity, to express anger or vengeance, to improve one’s living circumstances, in response to a delusion or hallucination, or as a result of impaired judgment (e.g., in dementia, mental retardation, substance intoxication).
F. The fire-setting is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder.

The Psychiatric Interview

The interviewer must bear in mind that the circumstances of arson, whatever the motive, may pose legal and criminal problems for the individual. This may provide motivation to skew the reporting of events. Individuals who may be at risk for the legal consequences of fire setting may be motivated to represent themselves as victims of psychiatric illness, hoping that a presumed psychiatric basis of the behavior may attenuate legal penalties. Thus, the interviewer must maintain a guarded view of the information presented.

Epidemiology

Most epidemiological studies have not directly focused on pyromania but instead on various populations of arsonists or fire setters. Most studies suggest that true pyromania is rare and reveal a preponderance of males with a history of fire fascination (Barker 1994). According to DSM-IV-TR, pyromania occurs more often in males, especially those with poorer social skills and learning difficulties. This notation confirms the Lewis and Yarnell (1951) data that only 14.8% of those with pyromania are female. Fire setting for profit or revenge or secondary to delusions or hallucinations is more frequent than “authentic” ICD. Although pyromania is a rare event, fire-setting behavior is common in the histories of psychiatric patients. Geller and Bertsch (1985) found that 50 (26%) of 191 nongeriatric state hospital patients had histories of some form of fire-setting behavior. Unlike pyromania, which is rare among women, fire-setting behavior was common in the histories of female patients (22%), as well as male patients (28.8%).

“True” pyromania in childhood is rare, but fire setting is frequent in children and in adolescents. Juvenile fire setting is most often associated with conduct disorder, ADHD, or adjustment disorder. Among children with psychiatric conditions, fire-setting behavior is quite common. Kolko and Kazdin (1988) found that among a sample of children attending an outpatient psychiatry clinic, approximately 20% had histories of fire setting. For a sample of inpatient children, the rate was approximately 35% (Kolko and Kazdin 1988).

The classic study Pathological Fire-Setting (Pyromania) by Lewis and Yarnell (1951) is one of the largest epidemiological studies of this topic and includes approximately 2000 records from the National Board of Fire Underwriters and cases provided from fire departments, psychiatric clinics and institutions, and police departments near New York City. Thirty-nine percent of the fire setters from the study received the diagnosis of pyromania. Twenty-two percent had borderline to dull normal intelligence, and 13% had between dull and low average intelligence. Fire setters were also described as driven by an irresistible impulse to set fires. The peak incidence of fire setting was between the ages of 16 and 18 years although. This observation has not been confirmed by more recent studies. The reported high prevalence rates of pyromania have not been confirmed by more recent studies. Koson and Dvoskin (1982) found no cases of pyromania in a population of 26 arsonists. Ritchie and Huff (1999) identified only 3 cases of pyromania in 283 cases of arson.
Comorbidity Patterns

Limited data are available regarding individuals with pyromania. Reported data of comorbid diagnoses are generally derived from forensic samples and do not distinguish between criminally motivated fire setters and compulsive fire setters. Fire-setting behavior may be associated with other mental conditions like mental retardation, conduct disorder, alcohol and other substance use disorders, personality disorders, and schizophrenia. In most cases, fire-setting behavior is not directly related to pyromania. On the other hand, fire setting in subjects who do not have pyromania appears frequent and often underrecognized. Among psychiatric patients, Geller and Bertsch (1985) found that 26% of the patients had a history of fire-setting behavior, and 16% of these patients had actually set fires. Ritchie and Huff (1999) reviewed mental health records and prison files from 283 arsonists, 90% of whom had a recorded history of mental health problems. Thirty-six percent had schizophrenia or bipolar disorder, and 64% were misusing alcohol or drugs at the time of their fire setting.

Repo et al. (1997) examined the medical and criminal records of 282 arsonists in order to compare first time and repeat offenders. They found that alcohol dependence and ASPD were common among recidivist offenders, especially among those who committed violent crimes. Recidivist offenders commonly had a history of enuresis during their childhood, were younger than first time offenders at the time of their first offence, and were more often intoxicated with alcohol during the arson attempt. Psychosis was common among those with no record of recidivist criminal offences. Puri et al. (1995) examined a group of 36 forensically referred fire setters. They found that about one-third had no other evidence of mental illness, about a quarter were female, psychoactive substance abuse was common and interpersonal relationships were often disturbed. Lejoyeux et al. (2002) assessed ICDs, using the Minnesota Impulsive Disorders Interview, in 107 depressed inpatients who met DSM-IV-TR criteria for major depressive episodes. Thirty-one depressed patients met criteria for ICDs: 18 had IED, 3 had pathological gambling, 4 had kleptomania, 3 had pyromania, and 3 had trichotillomania. Patients with pyromania had a higher number of previous deprivations (3.3 versus 1.3, \( P = 0.01 \)). Bipolar disorders were more frequent in the ICD group than in the group without ICDs (19% versus 1.3%, \( P = 0.002 \)).

Laubichler et al. (1996) compared the files of 103 criminal fire setters and subjects with pyromania. Subjects with pyromania were younger (average age 20 years) than criminal fire setters (average age 30 years). Seventy of the 103 subjects had consumed alcohol before setting a fire. Fifty-four percent presented with alcohol dependence. The authors suggested a correlation between the amount of alcohol consumed and the frequency of fire setting. Rååsåen et al. (1995) found that young arsonists have frequent alcohol problems: 82% had alcoholism and 82% were intoxicated at the time of committing the crime. The excessive consumption of alcohol had a close connection with the arson committed. Lejoyeux et al. (1999) searched for ICDs among consecutive admissions for detoxification of alcohol-dependent patients in a French department of psychiatry. They found 30 alcohol-dependent persons presenting with at least one ICD (19 with IED, 7 with pathological gambling, 3 with kleptomania, and 1 case of trichotillomania), but none of the patients presented with two or more ICDs, and no patient presented with pyromania. However, it cannot be concluded from such a limited population that pyromania is not associated with alcohol dependence. Further studies are needed.

Course

According to the DSM-TR, there are insufficient data to establish a typical age at onset of pyromania and to predict the longitudinal course. However, the impulsive nature of the disorder suggests a repetitive pattern. Again, because legal consequences may occur, the individual may be motivated to represent the index episode as a unique event. Fire setting for nonpsychiatric reasons may be more likely to be a single event. In individuals with pyromania, fire-setting incidents are episodic and may wax and wane in frequency. Studies indicate that the recidivism rate for fire setters ranges from 4.5% (Mavromatis and Lion 1977) to 28% (Lewis and Yarnell 1951). In a cross-sectional and 10-year follow-up study Barnett et al. (1997, 1999) compared mentally ill and mentally “healthy” fire setters from trial records in Germany where a defendant with a psychiatric disorder can be found to be not responsible, to have diminished responsibility, or to be fully responsible. Mentally disordered arsonists were more likely than those with no disorder to have a history of arson before their trial, were more often convicted of arson again (11% relapse compared with 4%), had fewer registrations of common offenses like theft, traffic violations, and alcohol-related offenses, had a higher rate of recurrence, and committed fewer common offenses other than fire setting. Among all arsonists who committed crimes in addition to arson, those who were found to be partly responsible for their arson committed the highest number of offenses followed by those who were deemed not responsible for their actions and those who were fully responsible.

Differential Diagnosis

Other causes of fire setting must be ruled out. Fire-setting behavior may be motivated by circumstances unrelated to mental disorders. Such motivations include profit, crime concealment, revenge, vandalism, and political statement or action (Geller 1987, Lowenstein 1989). Furthermore, fire setting may be a part of ritual, cultural, or religious practices in some cultures.

Fire setting may occur in the presence of other mental disorders. A diagnosis of fire setting is not made when the behavior occurs as a part of conduct disorder, ASPD, or a manic episode or if it occurs in response to a delusion or hallucination. The diagnosis is also not given if the individual suffers from impaired judgment associated with mental retardation, dementia, or substance intoxication.

Etiology and Pathophysiology

Because pyromania is rare, there is little reliable scientific literature available regarding individuals who fit diagnostic criteria. But because of the morbid impact that arson has on society, fire-setting behavior (which often does not fulfill criteria for pyromania) has been the focus of scientific investigation and literature.

Arson has been the subject of several investigations of altered neuroamine function. These findings include the observation that platelet monoamine oxidase is negatively correlated with fire-setting behavior of adults who...
had been diagnosed with attention-deficit disorder in childhood (Kupersmidt et al. 1988). Investigation of the function of serotonergic neurotransmission in individuals with aggressive and violent behaviors has included studies of CSF concentrations of 5-HIAA in individuals with a history of fire setting. 5-HIAA is the primary metabolite of serotonin, and its concentration in the CSF is a valid marker of serotonin function in the brain. Virkkunen et al. (1987, 1994) demonstrated that impulsive fire setting was associated with low CSF concentrations of 5-HIAA. This finding was consistent with other observations associating impulsive behaviors with low CSF 5-HIAA levels (like impulsive violence and impulsive suicidal behavior). A history of suicide attempt strongly predicts recidivism of arson (De Jong et al. 1992).

Impulse fire setters who are violent offenders are often dependent on alcohol and have an alcohol-dependent father (Linnola et al. 1989). Virkkunen et al. (1996) investigated biochemical and family variables and predictors of recidivism among forensic psychiatric patients who had set fires. Male alcoholic patients and fire setters (N = 114) were followed for an average of 4.5 years after their release from prison. Low CSF 5-HIAA and homovanillic acid concentrations were associated with a family history of paternal alcoholism with violence. A low plasma cholesterol concentration was associated with a family history positive for paternal alcoholism without violence. Compared with nonrecidivists, the recidivists, who set fires during the follow-up period, had low CSF 5-HIAA and MHPG (a metabolite of norepinephrine) concentrations and early family environments characterized by paternal absence and the presence of brothers at home.

Psychodynamic models refer to the symbolism of fire which is complemented by “normal” human interest in fire. Fire interest starts between the ages of 2 and 3 years and was almost universal in a study of normal schoolboys at the ages of 6, 8, and 10 years (Kafry, 1980). The distinction between normal interest in fire and excessive interest leading to pyromania is not always clear among children. Playing with matches is not a symptom of pyromania. Kolko and Kazdin (1989) showed that “future” pyromaniacs had more curiosity about fire and likely to be exposed to people (parents/peers) who are involved with fire. According to Geller and Bertsch (1985), children at risk of pyromania were more often involved in fire setting, threatening to set a fire, sounding a false fire alarm, or calling the fire department with a false report of fire than were control subjects. Thus, there may be a continuum between excessive interest in fire and “pure” pyromania.

Since the first description of pyromania in 1833 by the French psychiatrist Marc, the symbolic sexual dimension of pyromania has been noted. Many pyromaniacs were later described as having fire fetishes. A “fire experience” may become a “fire fetish” via conditioning with positive feedback by for example imagining/recalling a fire fantasy just before orgasm (McGuire et al. 1965). Lewis and Yarnell (1951) suggest three main groups of fire setters: the accidental, the occasional, and the habitual.

Treatment

Treatment Goals
Because of the danger inherent in fire-setting behavior, the primary goal is elimination of the behavior. The treatment literature does not distinguish between pyromania and fire-setting behavior of other causes. Much of the literature is focused on controlling fire-setting behavior in children and adolescents.

Psychiatrist-Patient Relationship
Because of the potential legal risks for people who acknowledge fire-setting behavior, the psychiatrist must take particular pains to ensure an environment of empathy and confidentiality. A corollary concern involves obligations that may be incumbent on the psychiatrist. Because of the legal implications of these behaviors and the potential for harm to another individual should fire setting recur, psychiatrists should consider both the ethical and the legal constraints that may follow from information learned in the course of treatment.

Somatic Treatments
There are no reports of pharmacological treatment of pyromania. Because fire setting may be frequently embedded in other psychiatric illness, therapeutic attention may be directed primarily to the underlying disorder. However, the dangerous nature of fire setting requires that the behavior be controlled. Much in the same fashion that one would seek to educate impaired patients about the functional risks associated with their symptoms—and to establish boundaries of acceptable behavior—the fire-setting behavior must be directly addressed, even if it is not a core symptom of the associated disorder.

Psychosocial Treatments
Treatment for fire setters is problematic because they frequently refuse to take responsibility for their acts, are in denial, have alcoholism, and lack insight (Mavromatis and Lion 1977). It has been estimated that up to 60% of childhood fire setting is motivated by curiosity. Such behavior often responds to direct educational efforts. In children and adolescents, focus on interpersonal problems in the family and clarification of events preceding the behavior may help to control the behavior (Lowenstein 1989). Principles of CBT have also been applied to childhood fire setting (Kolko 2001).

Treatments for fire setting are largely behavioral or focused on intervening in family or interpersonal stresses that may precipitate episodes of fire setting. Behavioral treatments like aversive therapy have helped fire setters (McGrath and Marshall 1979, Koles and Jenson, 1985). Other treatment methods rely on positive reinforcement with threats of punishment and stimulus satiation (Bumpass et al. 1983). Bumpass et al. (1983) treated 29 child fire setters and used a graphing technique that correlated external stress, behavior, and feelings on graph paper. After treatment (average follow-up, 2.5 years), only 2 of the 29 children continued to set fires. Relaxation training may also be used (or added to graphing techniques) to assist in the development of alternative modes of dealing with the stress that may precede fire setting. Another technique combines overcorrection, saturation, and negative practice with corrective consequences. The child is supervised in constructing a controlled, small fire in a safe location, which is then extinguished by the child. Throughout the process, the parent verbally instructs the child in safety techniques. Franklin et al. (2002b) confirmed the positive effect of a prevention program for pyromania. In
Clinical Vignette 2

A 34-year-old man came to a medical emergency department for the treatment of third-degree burns on his hands and face. He claimed to have been accidentally caught in a fire at a warehouse. Because of the patient's severe agitation and inability to explain the circumstances of the injury coherently, the treating surgeon asked that the patient be seen by a psychiatrist.

On meeting the psychiatrist the patient became even more severely agitated. He began to complain of the pain caused by his burns and was reluctant to speak with the psychiatrist. The patient insisted that he was in substantial pain and that he had no need to speak with "some shrink." Because the patient was going to be admitted for medical monitoring, the psychiatrist withdrew, planning to visit the patient again the next day in his hospital room. The next day the young man was more amenable to an interview. At this time he seemed sad and, although anxious, less visibly agitated than he was on the preceding day. He no longer questioned the psychiatrist's purpose in visiting him and participated in a brief discussion about his burns, the pain they caused, and the misfortune he suffered, having been caught in a fire. The psychiatrist again decided to withdraw after this brief conversation. Despite the passive cooperation the patient offered, the psychiatrist was still impressed with how guarded he seemed about the question of the events that led up to the fire. The psychiatrist concluded that the patient seemed to want to avoid discussing the details and decided that several visits might be necessary to engage the patient sufficiently to obtain an adequate history.

On the following day the patient seemed relieved when the psychiatrist entered the room. He said that he had something to tell the psychiatrist. He then proceeded to describe a history of fascination with fire since the age of 16 years. He had set a couple of small fires in wastebaskets at that age and found himself drawn to trade magazines that specialized in fire control equipment. He would often walk by the local firehouse and tried to follow the fire crews when they responded to a fire alarm. For a number of years he was aware of a growing urge to set fires. He worried about this compulsion and managed to avoid acting on it. In the past 3 years his forbearance began to erode. In that period he had set several fires in isolated parts of the city. He was careful to do so in areas where he knew few people might be caught in the fire. He tried to arrange circumstances in which the fire would be quickly discovered. Indeed, he reported one of the fires himself—both because he was fearful of the harm that might occur and because he had a great urge to see the firefighters arrive and battle the flames. In a recent fire a firefighter had been mildly injured. At that point he realized the dangers of his compulsion. Several days ago he went out to set another fire. He did not realize how quickly the fire would progress and he was injured. After telling the psychiatrist this story he expressed great relief that he finally had shared his shame with someone. He also expressed the hope that it would be understood that he suffered from a compulsion and asked the psychiatrist if there might be some way to reduce or erase the need to set fires. He realized he faced criminal prosecution but felt relieved that his behavior had been interrupted before another person was seriously hurt. Eventually this patient committed to treatment and his pyromania behavior remitted with a combination of cognitive-behavior therapy and medication treatment.

1999, they developed the Trauma Burn Outreach Prevention Program. All subjects arrested and convicted after setting a fire received 1 day of information. The program's interactive content focused on the medical, financial, legal, and societal impact of fire-setting behavior. The rate of recidivism was less than 1% in the group who attended the program, versus 36% in the control group.

Pathological Gambling

Definition and Diagnostic Features

Pathological gambling has been considered a distinct diagnostic entity since 1980, when it was first included

Pathological Gambling

A. Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following

1. Is preoccupied with gambling (e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble)

2. Needs to gamble with increasing amounts of money in order to achieve the desired excitement

3. Has repeated unsuccessful efforts to control, cut back, or stop gambling

4. Is restless or irritable when attempting to cut down or stop gambling

5. Gambles as a way of escaping from problems or of relieving a dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, depression)

6. After losing money gambling, often returns another day to get even (“chasing” one’s losses)

7. Lies to family members, therapist, or others to conceal the extent of involvement with gambling

8. Has committed illegal acts such as forgery, fraud, theft, or embezzlement to finance gambling

9. Has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling

10. Relies on others to provide money to relieve a desperate financial situation caused by gambling

B. The gambling behavior is not better accounted for by a manic episode.
in DSM-III (American Psychiatric Association 1980). DSM-IV-TR (American Psychiatric Association 2000) currently classifies pathological gambling as an ICD not elsewhere classified. Gambling as a behavior is common. Current estimates suggest that approximately 80% of the adult population in the US gamble. The amount of money wagered legally in the US grew from $17 to $210 billion in from 1974 to 1988, an increase of more than 1200%, making gambling the fastest growing industry in America at the time (Lesieur and Rosenthal 1991). DSM-IV-TR, like DSM-III-R before it, covertly recognized the ubiquity of gambling behavior and the desire to gamble by the careful wording of criterion A for pathological gambling: “Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following.” This definition of pathological gambling differs from some other definitions of ICDs not elsewhere classified, which are worded as “Failure to resist an impulse to.” This difference implies that neither gambling behavior nor failure to resist an impulse to engage in it is viewed as pathological in and of itself. Rather, the maladaptive nature of the gambling behavior is the essential feature of pathological gambling and defines it as a disorder.

**Assessment**

The most established measure for pathological gambling is the South Oaks Gambling Screen (SOGS) (Lesieur and Blume 1987, 1993). It is a 20-item questionnaire, which assesses recurrent and maladaptive gambling behavior that disrupts personal, family, and vocational pursuits. However, the SOGS has some limitations in that it does not correspond exactly with the DSM-IV diagnosis of pathological gambling or take into account frequency of gambling behaviors. While the SOGS is a self-report screening measure for PG, the Pathological Gambling Modification of the Yale-Brown Obsessive-Compulsive Scale (PG-YBOCS) (DeCaria et al. 1998b) is a clinician-rated outcome measure of PG. The PG-YBOCS consists of 10 questions that measure the severity and change in severity of pathological gambling symptoms over a recent time interval (usually within the past 1/2 week(s)). The first five questions assess urges and thoughts associated with pathological gambling, while the last five questions assess the behavioral component of the disorder. Although the PG-YBOCS is a relatively new measure of PG, it is one of the most widely used clinician-rated measures of PG. In addition to the SOGS and PG-YBOCS, the Gambling Symptom Assessment Scale (Kim et al. 2001) is a 12-item self-rated outcome measure designed to assess gambling symptom severity and change of gambling symptoms during treatment. It is an alternative pathological gambling measure that can be used in clinical studies.

It is not difficult to diagnose pathological gambling once one has the facts. It is much more of a challenge to elicit the facts, because the vast majority of patients with pathological gambling view their gambling behavior and gambling impulses as ego-syntonic and may often lie about the extent of their gambling (criterion A7). Patients with pathological gambling may first seek medical or psychological attention because of comorbid disorders. Given the high prevalence of addictive disorders in pathological gambling and the increased prevalence of pathological gambling in those with alcoholism and other substance abuse, an investigation of gambling patterns and their consequences is warranted for any patient who presents with a substance abuse problem. Likewise, the high rates of comorbidity with mood disorders suggest the utility of investigating gambling patterns of patients presenting with an affective episode.

The spouses and significant others of patients with pathological gambling deserve special attention. Individuals with pathological gambling usually feel entitled to their behavior and often rely on their families to bail them out (criterion A10). As a consequence, it is often the spouse of the patient with pathological gambling who first realizes the need for treatment and who bears the consequences of the disorder. Lorenz (1981) conducted a survey of 103 wives of pathological gamblers who attended Gam-Anon meetings (for family members of patients with pathological gambling). She found that most spouses had to borrow money and were harassed or threatened by bill collectors. Most spouses physically assaulted the gambler, verbally abused their children, and experienced murderous or destructive impulses toward the gambler. Although the gamblers themselves appeared less violent than the general population norms, their spouses were more violent, possibly because of desperation and anger. Eleven percent of the spouses of patients with pathological gambling admitted to having attempted suicide, and this result was replicated in a later study. These findings have two main implications for the assessment of pathological gambling: first, the spouse may be a valuable and motivated informant who should be questioned about the patient’s behavior, and second, spouses should be specifically asked about the effects of the patient’s illness on their own well-being and functioning and about suicidal ideation and attempts and the control of their own impulsivity.

**Epidemiology**

Pathological gambling is considered to be the most common of the ICDs not elsewhere classified. The number of people whose gambling behavior meets criteria for pathological gambling in the US is estimated to be between 2 and 6 million (Volberg and Steadman 1988). Surveys conducted between 1986 and 1990 in Maryland, Massachusetts, New York, New Jersey, and California estimated the prevalence of “probable pathological gamblers” among the adult population to be between 1.2% and 2.3%. These states have a broad range of legal wagering opportunities and a heterogeneous population. Similar surveys in Minnesota and Iowa, states with limited legal wagering opportunities and more homogeneous populations, yielded prevalence rates of 0.9% and 0.1%, respectively (Rosenthal 1992). Thus, availability of gambling opportunities and demographic makeup may influence the prevalence of pathological gambling. A 1998 study of national prevalence, using DSM-IV-TR criteria, determined that the prevalence of pathological gambling was 1.2% (1.7% for men and 0.8% for women). In addition to those who fulfilled DSM-IV-TR criteria, the researchers classified an additional 1.5% as “problem gamblers.” The combined total of “pathological gamblers” and “problem gamblers” is 5.5 million adult Americans (Gerstein et al. 1999). During the past 20 years, many states have turned to lotteries as a way of increasing their revenues without increasing taxes. Currently, some form of gambling is legal in 47 of the 50 states.
as well as in more than 90 countries worldwide. From 1975 to 1999 revenues from legal gambling in the US has risen from $3 to 58 billion (Vollberg 2002) thus the prevalence and incidence of pathological gambling are expected to increase. A meta-analysis of 120 published studies indicated that the lifetime prevalence of serious gambling (meeting DSM criteria for pathological gambling) among adults is 1.6% (Shaffer et al. 1999). Among those younger than 18 years, the prevalence is 3.9%, with past-year rates for adults and adolescents being 1.1% and 5.8%, respectively (Shaffer and Hall 1996). Although it is illegal for adolescents to gamble, this high rate may be due to illegal gambling of adolescents (e.g. via the internet or gambling with peers). Women make up about one-third of all Americans with pathological gambling. However, they are underrepresented in GA, in which only 2% to 4% of the members are women. This pattern is echoed in England and Australia, where women make up 7% and 10% of Gamblers Anonymous (GA) members, respectively. The reason for this discrepancy may be the greater social stigma attached to pathological gambling in women and their characteristic pattern of solitary gambling. Nonwhites and those with less than a high-school education are more highly represented among pathological gamblers than in the general population. The demographic makeup of patients in treatment for pathological gambling differs substantially from the demographics of all patients with pathological gambling. Jewish persons are overrepresented in treatment settings and in GA, while women, minorities, and those younger than the age of 30 years are underrepresented in GA and in treatment (Lesieur and Rosenthal 1991).

Comorbidity Patterns
Overall, patients with pathological gambling have high rates of comorbidity with several other psychiatric disorders and conditions. Individuals presenting for clinical treatment of pathological gambling apparently have impressive rates of comorbidity. Ibanez et al. (2001) reported 62.3% of one group seeking treatment had a comorbid psychiatric disorder. The most frequent current comorbid disorders were personality disorders (42%), alcohol abuse or dependence (33.3%), adjustment disorders (17.4%), and mood disorders (8.7%). Lifetime comorbid diagnoses included alcohol abuse or dependence (34.8%), mood disorders (15.9%), and anxiety disorders (7.2%). The relatively low rate of comorbid mood disorders compared to the rates reported below may be due to the outpatient setting of this study.

Mood Disorders
Pathological gambling is highly comorbid with affective disorders, among inpatient (McCormick et al. 1984) and outpatient samples (Linden et al. 1986). In several surveys, between 70% and 80% of all patients with pathological gambling also had mood symptoms that met criteria for a major depressive episode, a manic episode, or a hypomanic episode at some point in their life. More than 50% had recurrent major depressive episodes (Lesieur and Rosenthal 1991). A complicating factor is that recovering pathological gamblers may experience depressive episodes after cessation of gambling. In addition, some pathological gamblers may gamble to relieve feelings of depression (criterion A5). Despite criterion B for pathological gambling, which essentially precludes the diagnosis of pathological gambling if the behavior occurs exclusively during the course of a manic episode, many patients have a disturbance that meets criteria for both disorders because they gamble both during and between manic and hypomanic episodes. Between 32% and 46% of patients with pathological gambling were reported also to have mood symptoms that meet criteria for bipolar disorder, bipolar II disorder, or cyclothymic disorder (McElroy et al. 1992).

Suicide
Although data are not yet conclusive, a meaningful association between problem gambling and suicidal behavior and/or ideation appears to exist. Phillips et al. (1997) conclude that “Las Vegas, the premier US gambling setting, displays the highest levels of suicide in the nation, both for residents of Las Vegas and for visitors to that setting. In general, visitors to and residents of major gaming communities experience significantly elevated suicide levels. In Atlantic City, abnormally high suicide levels for visitors and residents appeared only after gambling casinos were opened. The findings do not seem to result merely because gaming settings attract suicidal individuals.” Others report that between 12% and 24% of pathological gamblers in various settings have had a history of at least one suicide attempt. In one study, 80% of pathological gamblers had a history of either suicide attempts or ideation (Lesieur and Rosenthal 1991).

Substance Abuse and Dependence
There appears to be a strong relationship between pathological gambling and substance abuse as evidenced by the high rates of comorbid substance abuse and dependency with pathological gambling (Lesieur et al. 1986, McCormick et al. 1984, Linden et al. 1986, Lesieur 1988). Studies of prevalence of comorbid substance use disorders yield widely varying results; from 9.9% for alcohol and other substance dependence (Gerstein et al. 1999) to 44% for alcohol dependence and 40% for illicit drug dependence (Bland et al. 1993, Cunningham-Williams et al. 1998). Using a structured instrument, between 5% and 25% of substance-abusing patients in several settings were found to meet criteria for pathological gambling and an additional 10% to 15% were considered to have “gambling problems” (Lesieur and Rosenthal 1991). Among individuals with pathological gambling, individuals with higher socioeconomic status (SES) are more likely to have concurrent problems with alcohol abuse then are gamblers with lower SES (Welt et al. 2001). Failure to treat comorbid substance use disorders in gamblers may lead to higher relapse rates (Maccallum and Blaszczynski 2002).

Other Disorders
Again, current data are inconclusive, but OCD, panic disorder, generalized anxiety disorder, and eating disorders have all been reported to be present in higher rates in patients with pathological gambling than in the general population. Pathological gambling has been described as being part of the obsessive-compulsive spectrum and sharing features with both OCD and impulsive cluster of obsessive-compulsive spectrum disorders (Dell’Osso et al. 2005, Bienvenu et al. 2000). The reported prevalence of OCD among pathological gamblers ranges from 0.9% (Cunningham-Williams et al. 1998) to 16% (Bland et al. 1993). Pathological gambling has
also been associated with ADHD (Carlton and Goldstein 1987). Retrospective studies suggest that many pathological gamblers have had symptoms that met criteria for ADHD as children (McElroy et al. 1992). Compulsive sexual behavior, compulsive buying disorder, and IED are relatively frequent in pathological gamblers, as are personality disorders. Murray (1993) found that pathological gamblers fit no particular personality profile, but several investigators have reported abnormal personality traits in pathological gamblers based on dimensional assessments (e.g., Roy et al. 1989). Taber et al. (1987) reported that 20% of 66 pathological gambling inpatients had personality disorders. Narcissistic and ASPD are believed to be overrepresented in these patients, and pathological narcissism is assumed by some psychoanalysts to underlie the entitlement displayed by many patients with pathological gambling. In addition to psychiatric disorders, patients with pathological gambling may manifest greater prevalence of stress-related medical conditions, like peptic ulcer disease, hypertension, and migraine.

Course

The onset of pathological gambling is usually insidious, although some may be “hooked” by their first bet. There may be years of social gambling with minimal or no impairment followed by an abrupt onset of pathological gambling that may be precipitated by greater exposure to gambling or by a psychosocial stressor. The gambling pattern may be regular or episodic, and the course tends to be chronic. Over time, there is usually a progression in the frequency of gambling, the amounts wagered, and the preoccupation with gambling and with obtaining money with which to gamble. The urge to gamble and gambling activity generally increase during periods of stress or depression, as an attempted escape or relief (criterion A5).

Pathological gambling usually begins in adolescence in men (Hollander et al. 2000a) with gradual development of dependence, and may remain undiagnosed for years, they often present with a 20- to 30-year-gambling history. In contrast, onset in females is usually later in life. Prior to seeking treatment, the duration of pathological gambling is about 3 years. Thus, as a result of the differences in onset and duration, female pathological gambers generally have a better prognosis than male pathological gamblers (Rosenthal 1992). Female pathological gamblers also tend to be depressed and may use gambling as an anesthetic, accompanied by excitation, to escape from life’s problems (i.e., as in a dissociative state; Jacobs 1988).

Psychiatric disorders like major depression and alcohol or substance abuse and dependence, may develop from or be exacerbated by pathological gambling. There is also a mortality risk associated with the disorder. Estimates of suicide attempts in pathological gamblers range from 17% to 24% (Ciarrochi and Richardson 1989, 2000a). One study found that the suicide rate in cities where gambling is legalized is four times higher than in cities where it is not (Phillips et al. 1997). Younger patients are more likely to have suicidal tendencies and major depressive disorders (McCormick et al. 1984), and most pathological gambling begins during adolescence (Hollander et al. 2000a), thus early identification and intervention are crucial.

Rosenthal (1992) described four typical phases in the course of a typical male patient with pathological gambling: winning, losing, desperation, and hopelessness (Linnoila et al. 1989).

Winning

Many male gamblers become involved with gambling because they are good at it and receive recognition for their early successes. Women with pathological gambling are less likely to have a winning phase. Traits that foster a winning phase and are typical of male patients with pathological gambling are competitiveness, high energy, ability with numbers, and interest in the strategy of games. The early winnings lead to a state in which a large proportion of the gambler’s self-esteem derives from gambling, with accompanying fantasies of winning and spectacular success.

Losing

A string of bad luck or a feeling that losing is intolerable may be the precipitant of chasing behavior; previous gambling strategies are abandoned as the gambler attempts to win back everything at once. The gambler experiences a state of urgency, and bets become more frequent and heavy. Debts accumulate, and only the most essential are paid. Covering up and lying about gambling become more frequent. As this is discovered, relationships with family members deteriorate.

Losing gamblers use their own and their family’s money, go through savings, take out loans, and finally exhaust all legitimate sources. Eventually, they cannot borrow any more, and faced with threats from creditors or loss of a job or marriage, they go to their family and finally confess. This results in the “bailout”: debts are paid in return for a promise to stop or cut down gambling. Any remission, if achieved, is short lived. After the bailout there is an upsurge of omnipotence; the gambler believes it is possible to get away with anything, bets more heavily, and loses control altogether.

Desperation

This stage is reached when the gambler begins to do things that would previously be inconceivable: writing bad checks, stealing from an employer, or other illegal activities. Done once, these behaviors are much more likely to be repeated. The behavior is rationalized as a short-term loan with an intention to pay it back as soon as the winning streak arrives. The gambler feels just one step away from winning and solving all the problems. Attention is increasingly taken up with illegal loans and various scams to make money. The gambler becomes irritable and quick tempered. When reminded of responsibilities or put in touch with guilt feelings, the gambler responds with anger and projective blame. Appetite and sleep deteriorate and life holds little pleasure. A common fantasy at this stage is of starting life over with a new name and identity, the ultimate “clean slate.”

Hopelessness

For some gamblers, there is a fourth stage in which they suddenly realize that they can never get even, but they no longer care. This is often a revelation, and the precise moment when it occurred is often remembered. From this point on, just playing is all that matters. Gamblers often acknowledge knowing in advance that they will lose and play sloppily so that they lose even if they have the right horse or a winning hand. They seek action or excitement for its own sake and gamble to the point of exhaustion.
Few gamblers seek help in the winning phase. Most do so only during the later phases and only after a friend, family member, or employer has intervened. Two-thirds of the gamblers have committed illegal activities by then, and the risk of suicide increases as they progress through the phases of the illness.

Without treatment, the prognosis of pathological gambling is poor. It tends to run a chronic course with increasing morbidity and comorbidity, gradual disruption of family and work roles and relationships, depletion of financial reserves, entanglement with criminals and the criminal justice system, and, often, suicide attempts. In the hands of an experienced psychiatrist, it is an “extremely treatable disorder” with a favorable prognosis (Rosenthal 1992). The difference between a poor and a good prognosis depends on treatment, and treatment depends on a diagnosis. As noted earlier, the diagnosis of pathological gambling is often missed in clinical settings because mental health professionals do not think to ask about it. Because most pathological gamblers do not see themselves as having a disorder and many of them do not even consider themselves as having a problem, collateral information from a family member may be very helpful.

**Differential Diagnosis**

The differential diagnosis of pathological gambling is relatively straightforward (Table 80–2). Pathological gambling should be differentiated from professional gambling, social gambling, and a manic episode. Social gambling, engaged in by a majority of adult Americans, typically occurs with friends or colleagues, lasts for a specified time, and is limited by predetermined acceptable losses. Professional gambling is practiced by highly skilled and disciplined people and involves carefully limited risks. Many individuals with pathological gambling may feel that they are actually professional gamblers. Chasing behavior and unplanned losses distinguish pathological gamblers. Patients in a manic episode may exhibit a loss of judgment and excessive gambling resulting in financial disasters. A diagnosis of pathological gambling should be given only if a history of maladaptive gambling behavior exists at times other than during a manic episode. Problems with gambling may also occur in people with ASPD. If criteria are met for both disorders, both can be diagnosed.

**Differences in Gender and Cultural Presentations**

An important and understudied area is the clinical presentation of pathological gambling in women. Women constitute a third of patients with pathological gambling in epidemiological studies. But, they are extremely underrepresented in treatment populations, and most psychoanalytic theories of pathological gambling ignore them completely. Part of this bias may be due to the fact that gambling carries a greater social stigma for women, women gamblers are more likely to live and to gamble alone, and treatment programs for pathological gambling in the US were first pioneered in Veterans Hospitals. Compared with men with pathological gambling, women with pathological gambling are more likely to be depressed and to gamble as an escape rather than because of a craving for action and excitement. Pathological gambling begins at a later age in female than in male gamblers, often after adult roles have been established. Big winning is usually less important than the need to impress. Women typically play less competitive forms of gambling in which luck is more important than skill, and they play alone. Their progression into the disorder is often more rapid, and the time between the onset of the disorder and the time they present for treatment is usually much shorter than for men (3 versus 20 years). The shorter duration makes for a better prognosis in treatment, but, unfortunately, few of the women with pathological gambling come to treatment.

The choice of gambling activities is dictated by local availability and cultural norms. Horseracing, cockfights, roulette, slot machines, casino card games, state-sponsored lotteries, and the stock market may all be used by the gambler. Likewise, the extent of gambling considered normal varies across cultures. DSM-IV-TR approaches this by concentrating on the consequences of gambling rather than on its frequency and type.

**Etiology and Pathophysiology**

Pathological gambling has been included in DSM-III, DSM-III-R, and DSM-IV as a disorder of impulse control. Pathological gambling can also be viewed as an addictive disorder (Murray 1993), an affective spectrum disorder (McElroy et al. 1992) and an obsessive-compulsive spectrum disorder (Hollander et al. 1992b). DSM-IV-TR maintains a close relationship between pathological gambling and addictive disorders in that several of the diagnostic criteria for pathological gambling were intentionally made to resemble criteria for substance dependence (Table 80–3).

The parallels between pathological gambling and addictive disorders are manifold. Pathological gambling has been viewed as the “pure” addiction, because it involves several aspects of addictive behavior without the use of a chemical

substance. The parallels between substance dependence, in particular alcohol dependence, and pathological gambling have led to the successful adoption of the self-help group model of Alcoholics Anonymous (AA) to GA. Patterns of comorbidity also suggest a possible link between pathological gambling and addictions, in particular alcoholism. In addition to the comorbidity of pathological gambling and substance use disorders, family studies have demonstrated a familial clustering of alcoholism and pathological gambling. Ramirez et al. (1983) found that 50% of their patients with pathological gambling had a parent with alcoholism; other studies have also found high rates of a family history of substance dependence in patients with pathological gambling. There is also a greater prevalence of pathological gambling in parents of patients with pathological gambling.

The links between pathological gambling and affective disorders are also supported by family studies that demonstrate high rates of affective disorders in first-degree relatives of patients with pathological gambling (McElroy et al. 1992), as well as by high rates of comorbidity of pathological gambling and affective disorders. In addition, as noted by many authors and incorporated in the DSM-IV-TR criteria for pathological gambling, many patients with pathological gambling gambled as a way of relieving dysphoric moods (criterion A5), and cessation of gambling may be associated with depressive episodes in the majority of recovering gamblers (Linden et al. 1986).

The links between pathological gambling and obsessive spectrum disorders are less clear. Although a popular name for pathological gambling is compulsive gambling, the majority of people with pathological gambling do not experience the urge to gamble as ego-dystonic until late in the course of their illness, after they have suffered some of its consequences. The rates of comorbidity of pathological gambling and OCD and obsessive-compulsive personality disorder are not nearly as high as the rates of comorbidity of pathological gambling and affective and addictive disorders. Nevertheless, pathological gambling shares several characteristics with compulsions: it is repetitive, often has ritualized aspects, and is meant to relieve or reduce distress. Moreover, sporadic reports on the effectiveness of SSRIs in the treatment of pathological gambling suggest a possible link to obsessive spectrum disorders (Hollander et al. 1992b).

Neurotransmitter Function

The association between altered function of the serotonin neurotransmitter system and impulsive behaviors has focused attention on a potential role for serotonin function in the neurophysiology of pathological gambling. Evidence of serotonergic dysfunction in pathological gamblers comes from neurobiological studies (Moreno et al. 1991, Carrasco et al. 1994, DeCaria et al. 1998a). These findings include: blunted prolactin response after intravenous administration

<tbody>
<tr>
<td><strong>A.</strong> Persistent and recurrent maladaptive gambling behavior as indicated by at least five (or more) of the following:</td>
<td>A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following:</td>
</tr>
<tr>
<td><strong>A1.</strong> Is preoccupied with gambling (e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble)</td>
<td>1. A great deal of time is spent in activities necessary to obtain the substance or recover from its effects</td>
</tr>
<tr>
<td><strong>A2.</strong> Needs to gamble with increasing amounts of money to achieve the desired excitement</td>
<td>2. (Tolerance) (a). A need for markedly increased amounts of the substance to achieve intoxication or desired effect or (b). markedly diminished effect with continued use of the same amount of substance</td>
</tr>
<tr>
<td><strong>A3.</strong> Has repeated unsuccessful efforts to control, cut back, or stop gambling</td>
<td>3. There is a persistent desire or unsuccessful attempts to cut down or control substance use</td>
</tr>
<tr>
<td><strong>A4.</strong> Is restless or irritable when attempting to cut down or stop gambling</td>
<td>4. (Withdrawal) (a). The characteristic withdrawal syndrome for the substance</td>
</tr>
<tr>
<td><strong>A5.</strong> Gambles as a way of escaping from problems or relieving a dysphoric mood</td>
<td>5. (Withdrawal) (b). The same substance is taken to relieve or avoid withdrawal symptoms</td>
</tr>
<tr>
<td><strong>A6.</strong> After losing money gambling, often returns another day to get even (“chasing” one’s losses)</td>
<td>6. The substance is often taken in larger amounts or over a longer period than was intended</td>
</tr>
<tr>
<td><strong>A7.</strong> Lies to family members, therapist, or others to conceal the extent of involvement with gambling</td>
<td>7. Important social, occupational, or recreational activities are given up or reduced because of substance use</td>
</tr>
<tr>
<td><strong>A8.</strong> Has committed illegal activities such as forgery, fraud, theft, or embezzlement to finance gambling</td>
<td>8. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance</td>
</tr>
<tr>
<td><strong>A9.</strong> Has jeopardized or lost a significant relationship, job, or educational opportunity because of gambling</td>
<td></td>

of the SSRI, clomipramine (Moreno et al. 1991), increased projection response after the administration of a serotonin agonist, m-CPP (DeCaria et al. 1996), and low platelet MAO-B activity (a correlate central nervous system concentrations of the serotonin metabolite 5-HIAA) (Blanco et al. 1996, Carrasco et al. 1994). However, direct measure of CSF 5-HIAA in pathological gamblers has yielded mixed results (Roy et al. 1988b, Bergh et al. 1997, Ibanez et al. 2002). Preliminary data support potential utility of SSRI medications in the treatment of pathological gambling (Hollander et al. 1998, 2000b, Ibanez et al. 2002). There is evidence of serotonergic dysfunction in depression (Coccaro et al. 1989), impulsivity (Linnoila et al. 1983), suicidality (Mann et al. 1992), and alcoholism (Tollefson 1989). This is of interest because pathological gambling is strongly associated with depression (Roy et al. 1988a, 1988b), impulsivity (Moreno et al. 1991), suicidality (Ciarrochi and Richardson 1989), and alcohol or drug abuse (Linden et al. 1986, McCormick et al. 1984). Thus, pathological gambling may also be associated with serotonergic dysfunction as it relates to these comorbid features.

Because of the “addictive” aspects of pathological gambling—and the role that dopaminergic function plays in chemical addictions—attention has been directed at dopamine function among pathological gamblers. Two available studies have yielded contradictory data (Roy et al. 1988b, Bergh et al. 1997). The role of noradrenergic function has also been explored. In support for such a role, pathological gamblers have been shown to have higher urinary and CSF concentrations of noradrenaline and metabolites (Roy et al. 1988b, Bergh et al. 1997). Measures of extroversion in pathological gamblers significantly correlate with indices of noradrenergic function (Roy et al. 1989). Further, increased noradrenergic function has also been associated with arousal, irritability, and risk-taking behavior (Coccaro et al. 1991) and pathological gambling has been associated with increased arousal and tonic activity of the central noradrenergic system (Brown 1986, Dickerson et al. 1987, Roy et al. 1988b). In addition, increased growth hormone secretion, a measure of noradrenergic reactivity, was found in pathological gamblers in response to oral administration of clonidine, an alpha-2-adrenergic agonist (Ibanez et al. 2002).

Genetic Contribution

The incidence of pathological gambling among first-degree family members of pathological gamblers appears to be approximately 20% (Ibanez et al. 2002). Inherited factors may explain 62% of variance in the diagnosis (Eisen et al. 1998) and some of these genetic factors may also contribute to the risk for conduct disorder, ASPD, and alcohol abuse (Eisen et al. 2001). Gambino et al. (1993) found that patients who perceived that their parents had gambling problems were three times more likely to score as probable pathological gamblers on the SOGS. Those who also perceived that their grandparents had gambling problems had a 12-fold increased risk compared with patients who did not perceive gambling problems in their parents and grandparents.

Serotonergic, noradrenergic, and dopaminergic genes have been investigated because of the putative role of these neurotransmitters in pathological gambling, and a number of molecular genetic studies performed to date have reported findings consistent with the involvement of these neurotransmitter systems in pathological gambling (e.g., Ibanez et al. 2001, Perez de Castro et al. 2002, Comings et al. 1996, 1997). However, some of the studies performed to date have not been adequately controlled for potential differences in racial and ethnic compositions, factors that could account for differences in allelic variant distributions. Thus, these studies should be regarded as preliminary.

At present, the main source of evidence for the genetic influence in the etiology of pathological gambling comes from a study of 3359 male twin pairs from the Vietnam Era Twin Registry cohort (Eisen et al. 1998, 2001, Slutske et al. 2000). These data suggest that gambling problems of increasing severity represent a single continuum of vulnerability rather than distinct entities (Eisen et al. 1998, 2001), a genetic susceptibility model in the pathogenesis of pathological gambling (Eisen et al. 1998), and indicates a common genetic vulnerability for pathological gambling and alcohol dependence in men (Slutske et al. 2000). In a smaller twin study, Winters and Rich (1999) found a significant heritability explaining “high action” gambling, like casinos and gambling slot machines, in 92 monozygotic and dizygotic male twin pairs. But, no significant differences in heritability were found among males for “low action” games and among 63 female monozygotic and dizygotic twin pairs for either “high action” or “low action” gambling.

Neuropsychology

Clinical comorbidities and observations that pathological gambling involves strong motivations to engage in gambling and subjective feelings of reward, withdrawal, and craving for gambling, support the categorization of pathological gambling as “a nonpharmacological addiction” (Blanco et al. 2001, Holden 2001). This view is corroborated by neuroimaging findings that gambling-associated cognitive and motivational events, or responses of pathological gamblers to gambling-related stimuli, are associated with metabolic changes in brain regions implicated in studies of substance use disorders (Breiter et al. 2001, Holden 2001, Potenza et al. 2003). Using FDG-PET in unmedicated pathological gamblers without comorbid substance use disorders (N = 7), Hollander et al. (2001) found heightened limbic and sensory activation in a gambling-for-money condition, with increased emotional valence and greater risk and reward, which confirms the salience of monetary reward in the development of pathological gambling.

Some data support the notion that people with impaired impulse control exhibit abnormalities in risk-benefit decision making in both gambling and nongambling activities and that their cognitive or emotional sense of what distinguishes gambling from other decisions of daily living may be compromised (Crean et al. 2000, Petry 2001a, 2001b; Petry and Casarella 1999, Bechara 2001, Bechara et al. 2000, 2001, Potenza 2001). These deficits may produce an inability to inhibit motivated drives to gamble, leading to persistent gambling. Myopia for the future and insensitivity to punishment has also been shown in orbitofrontal and ventromedial PFC lesion patients (Bechara et al. 1994, Berlin et al. 2004) using gambling tasks. Cavedini et al. (2002) data suggest a link between pathological gambling and other disorders (i.e., OCD and drug addiction) all having diminished ability to evaluate future consequences, which may be explained in part by an abnormal functioning of the orbitofrontal cortex.
Attention problems and impulsivity in pathological gamblers could reflect deficits in executive functioning that are often a consequence of minimal brain damage with orbitofrontal cortex impairment (Rugle and Melamed 1993, Specker et al. 1995, Berlin et al. 2004).

Psychodynamic Considerations
Psychoanalytic theories of gambling were the first systematic attempts to account for pathological gambling.Erotization of the fear, tension, and aggression involved in gambling behavior, as well as themes of grandiosity and exhibitionism, were explored by several authors during the first quarter of the 20th century. Freud (1961) in his influential essay on Dostoyevsky, suggested that the pathological gambler actually gambled to lose, not to win, and traced the roots of the disorder to the ambivalence felt by the young man toward his father. The father, the object of his love, is not only loved but also hated, and this results in unconscious guilt. The gambler then loses to punish himself, in what Freud labeled “moral masochism.” Freud also spoke of “feminine masochism” in which losing is a way of gaining love from the father, who will somehow reward the loser for loyalty. To lose is to suffer, and for the feminine masochist, suffering equals love. Interestingly, in the later spirit of DSM-IV-TR, Freud also conceptualized pathological gambling as an addiction and included it in a triad with alcoholism and drug dependence. He saw all three as manifestations of that primary addiction, masturbation, or at least masturbatory fantasies. Like most researchers after him, Freud focused only on male gamblers.

Bergler, a psychoanalyst who treated many pathological gambling patients, expanded on Freud’s idea that pathological gamblers gamble to lose (Lesieur and Rosenthal 1991). He traced the roots of this desire to lose to the rebellion of gamblers against the authority of their parents and the parents’ intrusive introduction of the reality principle into their lives. The rebellion causes guilt, and the guilt creates the need for self-punishment. Bergler thought that the gambler’s characteristic aggression is actually pseudoaggression, a craving for defeat and rejection. He saw the gambler as one who perpetuates an adversarial relationship with the world. The dealer in the casino, the gambler’s opponents at the card table, the stock exchange, and the roulette wheel are all unconsciously identified with the refusing mother or the rejecting father. Overall, psychoanalytic approaches to pathological gambling (Lesieur and Rosenthal 1991) generally conceptualized it as either a compulsive neurosis (Freud, Bergler, and Rosenthal) or an impulse disorder (Fenichel). Fenichel (1945) focused on the gambler’s entitlement and intense need to “get the stuff,” an oral fixation. Several published case reports documented the successful treatment of pathological gambling by psychoanalysis.

Learning theories of pathological gambling focus on the learned and conditioned aspects of gambling and use the quantifiable nature of the behavior to test specific hypotheses. One hypothesis was that patients with pathological gambling crave the excitement and tension associated with their gambling, as evidenced by the fact that they are much more likely to place last-second wagers than are low-frequency gamblers, to prolong their excitement. Higher wagers placed by patients with pathological gambling also produce greater excitement, and greater amounts of money are required to achieve the same “buzz” over time, an observation incorporated in the diagnostic criteria for pathological gambling (criterion A2).

Treatment
Treatment Goals
The goals of treatment of an individual with pathological gambling are the achievement of abstinence from gambling, rehabilitation of the damaged family and work roles and relationships, treatment of comorbid disorders, and relapse prevention. This approach echoes the goals of treatment of an individual with substance dependence. There are many similarities and several important differences between the treatment of pathological gambling and the treatment of substance dependence. For most patients without severe acute psychiatric comorbidity, such as major depressive disorder with suicidal ideation or alcohol dependence with a history of delirium tremens, treatment may be given on an outpatient basis. Inpatient treatment in specialized programs may be considered if the gambler is unable to stop gambling, lacks significant family or peer support, or is suicidal, acutely depressed, multiply addicted, or contemplating some dangerous activity.

No standard treatment of pathological gambling has emerged. Despite many reports of behavioral and cognitive interventions for pathological gambling, there are minimal data available from well-designed or clearly detailed treatment studies (Petry 2002). Pharmacological treatments (see below) offer promise, but research-guided approaches are still insufficient to offer a standardized approach. Thus, general approaches, based in clinical experience and available resources (like GA or other support groups) should be considered. The treatment of pathological gambling may consist of participation in GA, individual therapy, family therapy, treatment of comorbid disorders, and medication treatment. Many treatment modalities of pathological gambling are similar to that of substance abuse disorders and were created based on the addiction model, like self-help groups, inpatient treatment programs, and rehabilitation programs. As is the case for substance dependence, the gambler needs to be abstinent to be accessible to any or all of these treatment modalities. Essential features of any therapeutic intervention for pathological gambling include the need to establish both a therapeutic alliance and network, address the underlying pathology, interrupt the behavior and maintain abstinence, problem solve, and improve quality of life.

The most popular intervention for problem gambling is GA, a 12-step group built on the same principles as AA, which utilizes empathic confrontation by peers who struggle with the same impulses. For many gamblers, participation in GA is sufficient, and it is an essential part of most treatment plans. Extensive data are lacking, but overall GA appears somewhat less effective than AA in achieving and maintaining abstinence. Evidence suggests that GA may not be very effective when used without other treatment modalities (Petry and Armentano 1999). Retrospective studies show a dropout rate of up to 70% within the first year (Stewart and Brown 1988), and overall dropout rates range from 75% to 90% (Moody 1990). Only 8% of GA members report total abstinence at 1-year follow-up and 7% at 2-year
follow-up (Brown 1985). Although participation in GA's spousal component, Gam-Anon, may be helpful for some family members, little evidence suggests that it reduces disordered gambling (Petry and Armentano 1999).

Individual therapy is often useful as an adjunct to GA. Rosenthal (1992) stressed that to maintain abstinence and use GA successfully, many gamblers need to understand why they gamble. Therapy involves confronting and teasing out the vicissitudes of the patient's sense of omnipotence and dealing with the various self-deceptions and the defensive aspects of the patient's lying, and problems involving magical thinking and reality. Relapse prevention involves knowledge and avoidance of specific triggers. In addition to psychodynamic therapy, behavioral treatment of pathological gambling has been proposed, with imagined desensitization achieving better rates of remission than aversive conditioning.

The greatest differences between the treatment of pathological gambling and other addictions are in the area of family therapy. Because relapse may be difficult to detect (no substance smelled on their breath, dilated or constricted pupils, or slurred speech or staggered gait) and because of a long history of exploitative behavior by the patient, the spouse and other family members tend to be more suspicious of, and angry at, the pathological gambling patient compared with families of alcoholic patients. Family sessions are often essential to offer the gambler an opportunity to make amends, learn communication skills, and deal with preexisting intimacy problems. The spouse and other family members often acquire their own psychiatric illnesses during the course of the patient's illness and may need individualized treatment to recover.

**Somatic Treatments**

Although research reports of the pharmacological treatment of pathological gambling have reported some efficacy, there are still, as yet, insufficient data to come to any conclusions about the utility of medication. Pharmacological treatment studies of pathological gambling have demonstrated some promising results with the use of SSRIs (Hollander et al. 1992b, Hollander et al. 1998, 2000b, de la Gandara 1999, Zimmerman et al. 2002, Kim et al. 2003), serotonin reuptake inhibitors (Pallanti et al. 2002b), mood stabilizers (Haller and Hinterhuber 1994, Pallanti et al. 2002a, Hollander et al. 2002), opiate antagonists (Kim et al. 2001), and atypical antipsychotics (Potenza and Chambers 2001). Doses at the higher end of the usual treatment range should be considered with both SSRIs and opiate antagonists. Some studies have not reported significant findings, possibly due to high placebo response rates, high rates of discontinuation, as well as the possibility that different patients have differential responses to the various medication options based on endophenotypes that have yet to be elucidated (Blanco et al. 2002, Grant et al. 2003). At this time, pharmacological agent algorithms are still not definitive for the treatment of PG (Grant and Kim 2002e, Haller and Hinterhuber 1994, Hollander et al. 2000b, Kim and Grant 2001, Kim et al. 2001, Grant and Potenza 2004)). Treatment should ultimately target all symptom domains within the individual patient that contribute to compulsive gambling, including common comorbid conditions like bipolar spectrum disorder, ADHD, and substance abuse/dependence disorders.

**Psychotherapy**

Inpatient programs for pathological gambling have included various combinations of individual and group psychotherapy and substance use treatment (Taber 1981), and most strongly encouraged or required attendance at GA meetings. Many patients improved in all programs, and outcome studies have shown 55% of patients reporting abstinence at 1-year follow-up (Russo et al. 1984, Taber et al. 1987). Although methodologically flawed, these reports suggest that professionally delivered multimodal therapy programs, given alone or in combination with GA, may be more effective than GA alone. Self-help manuals may also be useful for some (Dickerson et al. 1990), and studies comparing their effectiveness with professionally delivered CBT are ongoing (Petry and Armentano 1999).

Early psychoanalytic reports suggest that problem gambling is regressive and representative of various pregeneric and genital instincts, unconscious conflicts, or painful affects. Most studies that report good outcome are based on single-case studies, and some authors believe that purely psychodynamic treatment of pathological gambling is difficult. Rosenthal and Rugle (1994) published a psychodynamic approach to pathological gambling treatment, which integrates traditional psychodynamic psychotherapy with an addiction model.

Behavioral, cognitive, and combined cognitive-behavioral methods have been used in treating pathological gambling. Aversive therapy has been employed to reach the goal of total abstinence of gambling, as have behavior monitoring, contingency management, contingency contracting, covert sensitization, systematic desensitization, imaginal desensitization, in vivo exposure, imaginal relaxation, psychoeducation, cognitive restructuring, problem-solving skills

---

**Clinical Vignette 3**

Mr. Z is a 44-year-old automobile mechanic who is married and has two adolescent children. He was referred for inpatient treatment from the emergency department of his local hospital after an overdose of a full bottle of over-the-counter sleeping pills taken as a suicide attempt. He took the pills in the setting of a major depressive episode without psychotic features. This was his first psychiatric contact. During his initial evaluation, Mr. Z admitted to several past depressive episodes for which he did not seek treatment and which resolved spontaneously. He also admitted to a history of alcohol abuse and stated that his drinking may have escalated recently. His family history was significant for a father with alcohol dependence and a mother with bipolar disorder. Mr. Z was treated as an inpatient with fluoxetine and improved rapidly, with full resolution of his suicidal ideation and other depressive symptoms.

Two days before his planned discharge from the hospital, a family meeting was held. During the meeting, his treatment team was surprised when his wife announced that she refused to let Mr. Z return home before “the other problem” was taken care of. At this point, a parallel history was taken and revealed that Mr. Z has had a problem with “excessive gambling” for the last 25 years. His wife meant that Mr. Z gambled with money that he did not have and went on gambling sprees that ended only when he lost all the money available to him and exhausted his current abilities to borrow money. During such episodes he had lost
Episodes may occur once or many times each day. Hairs are seen pulling out hair (Winchel 1992). Hair pulling tends to occur in small bursts that may last minutes to hours. The essential feature of trichotillomania is the recurrent failure to resist impulses to pull out one’s hair resulting in noticeable hair loss. An increasing sense of tension immediately before pulling out the hair or when attempting to resist the behavior. Pleasure, gratification, or relief when pulling out the hair. The disturbance is not better accounted for by another mental disorder and is not due to a general medical condition (e.g., a dermatological condition). The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Pulling out hairs may roam the afflicted area of scalp or body, searching for a shaft of hair that may feel particularly coarse or thick. Satisfaction with having pulled out a complete hair (shaft and root) is often expressed. Occasionally the experience of hair pulling is described as quite pleasurable. Some experience an itch-like sensation in the scalp that is eased by the act of pulling. The person may then toss away the hair shaft or inspect it. A substantial number of people then chew or consume the hair (trichophagia). Hair-pulling is most commonly limited to the eyebrows and eyelashes. The scalp is the next most frequently afflicted site. However, hairs in any location of the body may be the focus of hair-pulling urges, including facial, axillary, chest, pubic, and even perineal hairs.

Anxiety is almost always associated with the act of hair pulling. Such anxiety may occur in advance of the hair-pulling behavior. A state of tension may occur spontaneously, driving the person to pull out hair in an attempt to reduce dysphoric feelings. Varying lengths of time must pass before the tension abates. Consequently, the amount of hair that may be extracted in an episode varies from episode to episode and from person to person. Frequently, hair pulling begins automatically and without conscious awareness. In such circumstances, individuals discover themselves pulling out hairs after some have already been pulled out. In these situations, dysphoric tension is associated with the attempt to stop the behavior.

Circumstances that seem to predispose to episodes of hair pulling include both states of stress and, paradoxically, moments of relaxation. Frequently, hair pulling occurs when at-risk individuals are engaged in a relaxing activity that promotes distraction and ease (e.g., watching television, reading, talking on the phone). It is common for hair pullers to report that the behavior does not occur in the presence of other people. A frequent exception may be that many pull hair in the presence of members of the nuclear family.
Some individuals have urges to pull hairs from other people and may sometimes try to find opportunities to do so surreptitiously (like initiating bouts of play fighting). There have been reports of individuals pulling hairs from pets, dolls, and other fibrous materials, like sweaters or carpets (Tabatabai and Safari-Lak 1981).

The distress that usually accompanies trichotillomania varies in severity. Concerns tend to focus on the social and vocational consequences of the behavior. Themes of worry include fear of exposure, feeling that “something is wrong with me,” anxiety about intimate relationships, and sometimes inability to pursue a vocation. Because certain kinds of work, like reading and writing at a desk, seem to precipitate episodes of hair pulling, some individuals make career choices based on the avoidance of desk work. Leisure activities that may involve a risk of exposure (ranging from gymnastics class to sexual intimacy) may be avoided.

Patterns of hair-pulling behavior among children are less well described. Usually, the parent observes a child pulling out hair and may note patches of hair loss. Children may sometimes be unaware of the behavior or may, at times, deny it. Childhood trichotillomania has been reported to be frequently associated with thumb sucking or nail biting (Friman and Hove 1987). It has been suggested that trichotillomania with onset in early childhood may occur frequently with spontaneous remissions. Thus, some have recommended that trichotillomania in early childhood be considered a benign habit with a self-limited course. But, many people who present with chronic trichotillomania in adulthood report onset in early childhood (Reeve et al. 1992).

Assessment
In general, the diagnosis of trichotillomania is not complicated. The essential symptom—recurrently pulling out hair in response to unwanted urges—is easily described by the patient. When the patient acknowledges the hair-pulling behavior and areas of patchy hair loss are evident, the diagnosis is not usually in doubt. Problems in diagnosis may arise when the diagnosis is suspected but the patient denies it. Such denial may occur in younger individuals and some adults. When the problem is suspected but denied by the patient, a skin biopsy from the affected area (see later) may aid in making the diagnosis.

The Psychiatric Interview
The psychiatrist should carefully inquire into the nature of the distress and the patient’s concerns. Although the cosmetic impact may appear slight, distress may be severe. Concerns about disclosure, anticipation of social rejection, and concerns about limitations in career choices are frequent and may result in chronic dysphoria. The psychiatrist should be aware of the embarrassment that may accompany inspection of the hair loss, particularly when located in regions of the body that are not usually accessible in the course of a standard psychiatric examination. Because of the apparent frequency of comorbid mood disorders (past or current), the interviewer should pay special attention to the presence of these features.

Physical Examination and Laboratory Findings
Areas of hair loss can be marked by complete alopecia or can appear diffusely thinned or “ratty.” Altered scalp appearance can range from small areas of thinned hair to complete baldness. For unclear reasons, several patterns of scalp loss are typical. Frequently, coin-sized areas of alopecia are noted at the vertex or at temporal or occipital regions. Among more severely afflicted people a peculiar pattern, the so-called tonsure trichotillomania, may appear: a completely bald head except for a narrow, circular fringe circumscribing the outer boundary of the scalp, producing a look reminiscent of medieval friars.

Despite the hair loss, most individuals with this condition have no overtly unusual appearance on cursory inspection. If the hair loss is not covered by clothing or accessories, artful combing of hair or use of eyeliner and false eyelashes may easily hide it. The ease with which the condition may often be hidden may explain the general underappreciation of its apparent frequency and potential associated distress.

Associated Laboratory Findings
Histological findings are considered characteristic and may aid diagnosis when it is suspected despite denial by the individual. Biopsy samples from involved areas may have the following features. Short and broken hairs are present. The surface of the scalp usually shows no evidence of excoriation. On histological examination, normal and damaged follicles are found in the same area, as well as an increased number of catagen (i.e., nongrowing) hairs. Inflammation is usually minimal or absent. Some hair follicles may show signs of trauma (wrinkling of the outer root sheath). Involved follicles may be empty or contain a deeply pigmented keratinous material. The absence of inflammation distinguishes trichotillomania-induced alopecia from alopecia areata, the principal condition in the differential diagnosis (Mehregan 1970, Muller 1990).

Epidemiology
Trichotillomania was long thought to be uncommon, often accompanied by other psychiatric conditions. Although definitive studies of frequency rates in the general population are still lacking, three surveys of nonclinical college-age samples support the emerging view that trichotillomania is more common than originally suggested. In two of these samples, totaling approximately 3000 undergraduate students, 10–13% of students reported hair pulling, with the prevalence of clinically significant pulling ranging between 1% and 3.5% (Christenson et al. 1991b, Rothbaum et al. 1993). A epidemiological study of trichotillomania and skin picking using self-report instruments (the Massachusetts General Hospital Hairpulling Scale and the Skin Picking Scale) in a sample of 1324 college freshmen found that 5.4% (72) endorsed relatively frequent hair pulling or skin picking (Hajcak et al. 2006). One epidemiological survey of 17-year-old adolescents in Israel suggests a prevalence rate of 1% for current or past hair pulling, with fewer reporting noticeable hair loss or distress from these symptoms (1995a).

These may be underestimates of the lifetime incidence of the disorder. Had these studies applied DSM-IV-TR criteria, which have become slightly less restrictive than DSM-III-R criteria, the rates might be higher. In addition, because onset may occur later in life than the mean ages of individuals in these groups, the true lifetime incidence would probably be higher. Moreover, these samples consist of a
selected population—largely first-year college students—and may not reflect the general population. Nonetheless, these studies indicate that the condition is likely to be far more common than previously assumed. But definitive, controlled studies of the prevalence of the condition have not yet been performed.

**Comorbidity Patterns**

Many experts (e.g., Christenson and Mansueto 1999) have noted a common co-occurrence and formal similarities between trichotillomania and other body-focused ICDs like skin picking and severe nail biting. Nail biting and skin picking (excoriation) are often associated with trichotillomania and these three pathological behaviors often co-occur with each other and are thought to be related (Wilhelm and Margraf 1993, Bhatia et al. 1991, Simeon et al. 1997, O’Sullivan et al. 2000, Cohen et al. 1995, Wilhelm et al. 1999). If the skin-picking and nail-biting appear to be largely negatively reinforcing—that is, reducing anxiety associated with specific obsessional thoughts and/or reducing the likelihood of feared outcomes—they may be better conceptualized as OCD behaviors and addressed accordingly. However, Franklin et al. (2006) suggest, based on clinical experience, that these conditions are much more likely to formally resemble trichotillomania. In accordance, many trichotillomania patients have comorbid skin picking and nail biting (O’Sullivan et al. 2000, Lochner et al. 2002, Christenson et al. 1991a, Simeon et al. 1997).

Individuals with trichotillomania have increased risk for mood disorders (major depressive disorder, dysthymic disorder) and anxiety symptoms (Table 80-4). The frequency of specific anxiety disorders (like generalized anxiety and panic disorders and OCD) may be increased as well. Compared to controls, college students who reported frequent hair pulling or skin picking also reported significantly more symptoms of anxiety and stress reactivity, and had higher scores on a measure of obsessive-compulsive symptoms (Hajcak et al. 2006). Although it has been suggested that trichotillomania in childhood or adolescence is associated with schizophrenia or severe disruptions of the family system, no systematically collected data support such conclusions.

Christenson et al. (1991a) found that approximately 82% of an adult sample with trichotillomania met criteria for a past or current comorbid Axis I disorder, the most common being affective, anxiety, and addictive disorders. Of the patients with comorbid disorders, there was a lifetime prevalence rate of 65% for mood disorders, 57% for anxiety disorders, 22% for substance abuse disorders, 20% for eating disorders, and 42% for personality disorders. The most frequently cited comorbid personality disorders are histrionic, borderline, and obsessive-compulsive (Christenson et al. 1992, Schlosser et al. 1994, Swedo and Leonard 1992). In a larger sample of adults seeking treatment for trichotillomania, Christenson (1995) found comorbidity rates of 57% for major depression, 27% for generalized anxiety disorder, 20% for eating disorders, 19% for alcohol abuse, and 16% for other substance abuse. In a mixed sample of children, adolescents, and adults with trichotillomania, Swedo and Leonard (1992) found comorbidity rates of 39% for unipolar depression, 32% for generalized anxiety disorder, 16% for OCD, and 15% for substance abuse. Reeve et al. (1992) and King et al. (1995b) found that 7 of 10 and 9 of 15 children with trichotillomania had at least one comorbid Axis I disorder, respectively. Franklin et al. (2002a) and Tolin et al. (2002) reported little comorbidity in their pediatric treatment-seeking samples, suggesting that comorbidity may develop secondarily in the wake of trichotillomania. Sampling issues most likely underlie these observed differences. Nevertheless, if it is indeed the case that children and adolescents with trichotillomania are less comorbid than adults, early intervention in children and adolescents with trichotillomania may help reduce the rates and severity of later adult psychiatric comorbidity and functional impairment (Keuthen et al. 2002).

**Course**

The age at onset typically ranges from early childhood to young adulthood. Peak ages at presentation may be bimodal, with an earlier peak about age 5 to 8 years among children in whom it has a self-limited course, whereas among patients who present to clinicians in adulthood the mean age at onset is approximately 13 years (Rothbaum et al. 1993, Winchel 1992, Swedo et al. 1989). Initial onset after young adulthood is apparently uncommon. There have been reports of onset as early as 14 months of age and as late as 61 years.

Trichotillomania may be one of the earliest occurring conditions in psychiatry. Some parents insist that their child began pulling hair before 1 year of age. When trichotillomania begins before age 6 years it tends to be a milder condition. It often responds to simple interventions and may be self-limited, with a duration of several weeks to several months, even if not treated. It often occurs in association with thumb sucking. In some cases it remits spontaneously when therapeutic attention is directed at concurrent, severe thumb-sucking (Watson and Allen 1993). It has been suggested that trichotillomania in childhood may be associated with severe intrapsychic or familial psychiatric conditions. But there is no reliable evidence that supports such a conclusion. Indeed, some have suggested that because it may be common and frequently self-limiting, it should be considered a normal behavior among young children.

Tricotillomania in adolescents and adults typically follows a chronic course, involves multiple hair sites, and

<sup>†</sup>Patients with OCD were excluded from this sample, as were patients with psychosis.
is associated with high rates of psychiatric comorbidity (Christensen et al. 1991a). The chronic course may take one of two patterns; in one the frequency and severity of hair pulling waxes and wanes over months, without any true remissions; in the other, episodes are characterized by frequent hair pulling separated by long periods of remission (Moore and Jefferson, 2004). Some individuals have continuous symptoms for decades. For others, the disorder may come and go for weeks, months, or years at a time. Sites of hair pulling may vary over time. Circumscribed periods of hair pulling (weeks to months) followed by complete remission are reported among children. Progression of the condition appears to be unpredictable. It is not known which factors may predict a protracted and unremitting course.

Because of the unavailability of longitudinal studies of trichotillomania, generalizations about prognosis cannot be made. Patients who present in research clinics typically have histories of many years (up to decades) of hair pulling. Presentation after age 40 years appears to be far less common than in the previous three decades of life, suggesting that the condition may eventually remit spontaneously, even when untreated. It is likely that the persistent cases seen in research environments reflect the more severe end of the spectrum. As noted earlier, trichotillomania in children may often be a time-limited phenomenon.

Differential Diagnosis

Among individuals presenting with alopecia who complain of hair-pulling urges, the diagnosis is not usually in doubt. When patients deny hair pulling, other (dermatological) causes of alopecia should be considered. These include alopecia areata, male pattern hair loss, chronic discoid lupus erythematosus, lichen planopilaris, folliculitis decalvans, pseudopelade, and alopecia mucinosa.

Trichotillomania is not diagnosed when hair pulling occurs in response to a delusion or hallucination. Many people twist and play with their hair. This may be exacerbated in states of heightened anxiety but does not qualify for a diagnosis of trichotillomania. Some may present with features of trichotillomania but hair damage may be so slight as to be virtually undetectable, even under close examination. In such conditions the disorder should be diagnosed only if it results in significant distress to the individual.

Trichotillomania may have a short, self-limited course among children and may be considered a temporary habit. Therefore, among children the diagnosis should be reserved for situations in which the behavior has persisted during several months.

Differences in Gender and Cultural Presentations

Secondary avoidance of intimate relationships, which occurs among some individuals with trichotillomania, may be exacerbated for women in cultures in which physical appearance is weighted differently for men and women. Avoidance of sports activities, in which disguised hair loss can be revealed, can also have gender-related effects in cultures in which athletic participation has different social meanings for men and women. Although culture-based expectations regarding appearance may make hair loss a greater burden for women, women may have a greater opportunity to hide hair loss through the use of wigs, hats, and scarves.

Reliable data regarding sex ratio in the general population are not yet available. It has long been suggested that women greatly outnumber men. However, surveys of college students suggest that the true ratio may be near parity. The apparent preponderance of women presenting for treatment may alternatively reflect self-selection for presentation for treatment. Self-selection may reflect gender related, culturally based attitudes regarding appearance, as well as an acceptance of normative hair loss among men. Because such gender-related distinctions may not be made by parents who are concerned about hair-pulling habits in their children, the apparent equal presentation of male and female children may more accurately reflect the true sex ratio. For many women, hair pulling may worsen during the premenstrual phase (Keuthen et al. 1997).

Etiology and Pathophysiology

The etiology of trichotillomania is unknown. The phenomenological similarities between trichotillomania and OCD have prompted speculations that the pathophysiology of the two conditions may be related. The apparent association between altered serotonergic function and OCD has guided attention toward the possible role of serotonergic function in the underlying cause of trichotillomania. Thus, interest has been spurred in examining serotonergic function in patients with trichotillomania.

Ninan et al. (1992) obtained CSF from eight individuals with trichotillomania and measured concentrations of the primary serotonin metabolite 5-HIAA. Baseline concentrations of 5-HIAA did not differ from those of control subjects, nor was there a relationship between the baseline 5-HIAA concentration and the severity of trichotillomania symptoms. But, seven of these patients were then treated with SSRIs (fluoxetine and clomipramine). The researchers found a negative correlation between baseline CSF 5-HIAA concentration and the degree of improvement after treatment. This observation does not, however, directly support a conclusion that altered serotonin function is etiologically related to trichotillomania.

Swedo et al. (1991) used PET to measure regional brain glucose in three groups: trichotillomania patients, OCD patients, and normal controls. Like OCD patients, those with trichotillomania had altered patterns of glucose utilization compared with normal controls. However, the regional patterns of altered glucose utilization differed between trichotillomania and OCD groups. In a morphometric MRI study, left putamen volume was found to be significantly smaller in 10 female trichotillomania subjects as compared with 10 normal matched controls (O’Sullivan et al. 1997).

Performance on neuropsychological tests may offer an additional basis for defining the underlying neuropathological process in people with trichotillomania. Because impaired performance on such tests may indicate altered function in particular brain regions, they may also help localize brain regions in which altered function may be associated with trichotillomania. On the basis of such tests, Rettew et al. (1991) suggested that trichotillomania patients may have deficits in spatial processing. Patterns of deficits on such tests may provide further support for a relationship between trichotillomania and other psychiatric conditions. Rettew et al. (1991) found similarities between trichotillomania and OCD subjects.
Keuthen et al. (1996) also speculated that people with trichotillomania would demonstrate alterations in neuropsychological function similar to individuals with OCD, who have been shown to have impairments in executive, visual-spatial, and nonverbal memory function. In a study of 20 trichotillomania subjects and 20 matched healthy controls, they demonstrated the presence of impaired performance on two of these three parameters (nonverbal memory and executive function). These results were interpreted as supporting the presumed relationship between trichotillomania and OCD. However, Stanley et al. (1997a), in their study of 21 trichotillomania subjects versus 17 healthy controls, did not find evidence of deficits in visual-spatial ability, motor function, or executive function. But, differences were found on measures of divided attention, leading to the suggestion that trichotillomania might be more properly conceptualized as an affective or anxiety-based disorder, and that any demonstrated similarities with OCD may be related to their shared overlap with anxiety/affective disorders.

Additional support for a possible relationship between trichotillomania and OCD may come from family studies. In a preliminary investigation of psychiatric diagnoses among first-degree relatives of probands with trichotillomania, Lenane et al. (1992) found increased frequencies (compared with normal control subjects) of OCD, as well as mood and anxiety disorders. Bienvenu et al. (2000) examined 300 first-degree relatives of 343 OCD patients, and found increased rates of “grooming” conditions (e.g., nail-biting, skin-picking, trichotillomania), and other ICDs (e.g., kleptomania, pathological gambling, pyromania).

In sum, few data are available to support any particular model of the etiological pathophysiology of trichotillomania. Early studies point to some alteration of brain activity. There is inconsistent support in these studies for a relationship with OCD. Figure 80-2 shows a schematic diagram of a preliminary biopsychosocial model of trichotillomania (Franklin et al. 2006). This model is heuristic, not explanatory, but is hoped to stimulate new studies on the mechanisms of trichotillomania and to be modified as new data emerges.

Treatment

Treatment Goals
Treatment of trichotillomania typically occurs in an outpatient setting. Eradication of hair-pulling behavior is the general focus of treatment. Distress, avoidant behaviors, and cosmetic impairment are secondary to the hair-pulling behavior and would be likely to remit if the hair-pulling behavior is controlled. However, if sufficient control of hair pulling cannot be attained, treatment goals should emphasize these associated problems as well. Even if hair pulling persists, therapeutic interventions may be targeted at reducing secondary avoidance and diminishing distress. Treatment may be considered in three phases:
Initial Contact: The diagnosis is made and the patient and psychiatrist agree on a strategy that may incorporate both pharmacological and psychological interventions. If distress is severe, supportive interventions should be immediately considered in anticipation of incomplete treatment response or of a delay of weeks to months before interventions may be beneficial.
Acute Treatment: Even when treatment of hair-pulling behavior is optimally successful, there may be a delay of several weeks to months before adequate control is attained. So, the acute treatment phase may be prolonged.
Maintenance: It is not known how long patients must maintain active treatment interventions to prevent relapse. It should be anticipated that a substantial number of patients require ongoing treatment for an extended time. Pharmacological treatments may need to be maintained for open-ended periods. Behavioral or hypnotic intervention may require periodic “booster shots” to support continuation of benefits.

Psychiatrist-Patient Relationship
It is important to bear in mind the particular nature of embarrassment that often accompanies this condition. Several factors contribute to feelings of shame for many with trichotillomania. When hair pulling has had its onset in childhood or adolescence, there is often a history of the hair pulling being treated as a family secret. Patients have been frequently castigated by parents or spouses for lack of self-control. There may also be a feeling that the problem is largely cosmetic, causing some individuals to fear they do not have the “right” to utilize health resources for its treatment. This may be manifest as fears of having their problem minimized or of being derided for seeking help. It is helpful for the clinician to share with patients an understanding that the problem pervades their daily life and may result in meaningful distress and functional inhibition.

A variety of treatment approaches have been advocated for trichotillomania. However, there have, as yet, been few controlled studies of the efficacy of any treatment approach. A review of the literature reveals that only eight randomized trials have been conducted thus far, seven of which included a control condition (see below). A number of investigations of the use of antidepressants with specific inhibition of serotonin reuptake (i.e., fluoxetine and clomipramine) have yielded mixed results (Rothbaum et al. 1993, Winchel et al. 1992, Swedo et al. 1989, Stein et al. 1997, Jaspers 1996). A multicomponent approach, simultaneously utilizing several complementary treatment options, may turn out to be the most effective approach for most patients.

While a number of treatment options can be currently offered to individuals with trichotillomania, the durability of long-term outcomes is unclear. Keuthen et al. (1998, 2001) followed a group of hair pullers who had “naturalistic” treatment in the community. Treatments were pharmacological, behavioral or both. Among those who had benefits, improvements were often lost over time, and persistent treatment and ongoing treatment was common over the course of several years.

Stress Management
Before embarking on a course of treatment, the psychiatrist and the patient should first consider the course and severity of the individual’s condition. Because early remission may occur in cases of recent onset, mild trichotillomania of short duration does not necessarily require immediate intervention. In particular, if the hair pulling first occurred during a
period of stress, the behavior may spontaneously diminish as the stressful circumstances abate. In such circumstances, therapeutic attention may best be directed toward examining and seeking to diminish the basis for stress. Teaching alternative stress reduction methods may be useful in reducing recent-onset trichotillomania. However, when individuals with trichotillomania present to the psychiatrist, it is often likely to have been a persistent condition and may have been present for many years or decades. Among such patients, stress reduction may also be useful in reducing trichotillomania but complete remission is less likely.

Somatic Treatments

The literature is generally made up of case studies, with progressively more controlled investigation in recent years. In general, knowledge about trichotillomania treatments is limited by small sample sizes, lack of specificity regarding sample characteristics, nonrandom assignment to treatment, dearth of long-term follow-up data, exclusive reliance on patient self-report measures, and lack of information regarding rates of treatment refusal and dropout.

A variety of medications have been used in the treatment of trichotillomania. In 1989, initial reports demonstrated the apparent benefits of fluoxetine and clomipramine. Clomipramine was found to be superior to desipramine (Swedo et al. 1989). Fluoxetine was reported beneficial in open treatment (Winchel et al. 1992). Although reports for more than 60 patients have subsequently added support for the use of these medications, the two double-blind studies in which fluoxetine has been compared with placebo did not demonstrate any improvement compared to placebo (Christenson et al. 1991b, Streichenwein and Thornby 1995). Fluvoxamine (Stanley et al. 1997b), citalopram (Stein et al. 1997), escitalopram (Gadde et al. 2007), and venlafaxine (Ninan et al. 1998) have been reported to be efficacious in open trials. Although more controlled trials of SSRIs are needed, the use of such medications would be a prudent first step if a pharmacological approach has been agreed upon.

Of the six randomized, controlled trials evaluating the efficacy of pharmacotherapy conducted to date, five involved SSRIs. This may reflect the previously prevailing view that trichotillomania is a variant of OCD and thus ought to be responsive to the same pharmacological agents proven successful in for OCD. In sum, results from these controlled studies of SSRIs are equivocal at best, although in view of the small sample sizes more controlled research should be conducted to determine their efficacy (Swedo et al. 1989, 1993, Christenson et al. 1991c, Streichenwein and Thornby 1995, Ninan et al. 2000, van Minnen et al. 2003). Perhaps important differences between OCD and trichotillomania underlie this apparent difference in treatment response. However, several case studies indicated that augmentation of SSRIs with atypical neuroleptics may be beneficial (Epperson et al. 1999, Stein and Hollander 1992), and an open trial suggested that olanzapine may be efficacious as a monotherapy for trichotillomania (Stewart and Nejtek 2003). Interestingly, naltrexone, an opioid antagonist, thought to decrease positive reinforcement, has also been found superior to placebo in reducing trichotillomania symptoms (Christenson et al. 1994).

Although no double-blind discontinuation studies have been conducted in trichotillomania, evidence from open studies suggests that treatment response gained from pharmacotherapy may not be maintained in the long run (Pollard et al. 1991, Iancu et al. 1996). The absence of a single randomized, controlled trial in pediatric trichotillomania limits treatment recommendations for this population.

Initial evidence of improvement is usually first reported by the patient as greater awareness of the inclination to pull hair. This is usually followed by an ability to abort hair-pulling episodes more quickly than in the past. The ability to resist the urge follows. In cases with a good outcome, the inclination to pull diminishes and may eventually disappear. Patients who pull from several sites may find that the rate of improvement varies from site to site.

There have been conflicting reports of early relapse of symptoms in some patients treated with clomipramine or fluoxetine. Although good maintenance of benefit has been reported for some patients 6 months and longer after the initiation of treatment, early relapse after several weeks to months has also been reported. Keuthen et al. (2001) provided long-term data on maintenance of response over time. Following a group of people who had varying forms of treatment (pharmacological and psychological) for several years after an index evaluation, the authors concluded that initial improvement was common, but over time there was an increase in symptom scores and self-esteem scores worsened. This problem needs further exploration in long-term treatment studies. If early relapse turns out to be common, it would distinguish trichotillomania from depression and OCD, in which medication benefits are often well maintained as long as medication is continued. Optimal duration of treatment for well-treated individuals is still unknown. In accord with standards developed for the treatment of other conditions, it would be reasonable to continue medication for at least 6 months before tapering. Reinitiation of treatment may be needed.

In a 16-week open trial, the anticonvulsant drug topiramate, which has shown promising results in the treatment of ICDs, significantly decreased the severity of hair pulling in adults with trichotillomania (Lochner et al. 2006). Christenson et al. (1991c) have reported successful treatment with lithium. This observation awaits replication. Because trichotillomania is often accompanied by other manifestations of anxiety—and for many individuals is exacerbated by stressful conditions—attempts at treatment with anxiolytic agents may be useful as well. There are no published reports of such treatments.

Adjunctive treatment with pimozide, a neuroleptic agent, has been advocated for some patients who are refractory to other medications (Stein and Hollander 1992). The potential benefits of neuroleptics have been reported now by several authors (Potenza et al. 1998, Gabriel 2001, Gupta and Gupta 2000, Epperson et al. 1999). Most of these reports describe individuals for whom SSRIs provided insufficient benefits. The addition of atypical neuroleptics much improved their outcomes. The greater margin of safety and tolerability associated with atypical neuroleptics may make this a more viable treatment option, but the potential side effects of atypicals should still be taken into consideration. Van Ameringen et al. (1999) found that eight of nine trichotillomania patients responded to haloperidol. Six previously failed treatment with SSRIs. The possible superiority of neuroleptics prompted these authors to speculate
that trichotillomania may be similar to Tourette’s syndrome, which responds preferentially to neuroleptics.

**Psychosocial Treatments**

**Behavioral Treatment**

Various behavioral techniques have been tried (Diefenbach et al. 2000). The most successful technique, habit reversal, is based on designing competitive behaviors that should inhibit the hair-pulling behavior (Azrin and Nunn 1977, Azrin et al. 1980, Rosenbaum and Ayllon 1981). For example, if hair pulling requires raising the arm to the scalp and contracting the muscles of the hand to grasp a hair, the behaviorist may design a behavioral program in which the patient is taught to lower the arm and extend the muscles of the hand. As with most behavioral techniques, these interventions are most successful when the patient is strongly motivated and compliant. Also, the treating psychiatrist should be experienced in the use of such techniques. If necessary, a referral should be made to an experienced individual. Modified behavioral approaches have been described for children and adolescents (Vitulano et al. 1992, Rapp et al. 1998).

In a randomized, controlled trial (Diefenbach et al. 2006), patients completing group behavior therapy (n = 12) experienced significantly greater decreases in self-reported hair-pulling symptoms and clinician-rated hair loss severity than those in group supportive therapy (n = 12). In addition, a significantly higher percentage of those in the behavior therapy condition were rated as much improved or very much improved on the Clinical Global Impression scale at posttreatment. But, despite substantial symptom improvement, trichotillomania severity remained problematic at posttreatment, few patients in either treatment met criteria for clinically significant change at posttreatment, and relapse of symptoms occurred over the 6-month follow-up period. So these results provided support for the short-term efficacy of group behavior therapy.

**Cognitive-Behavioral Therapy**

CBT has been developed for, and applied to, trichotillomania patients. A variety of techniques have been used, and although the current CBT literature justifies only cautious recommendations, habit reversal, awareness training, and stimulus control are generally purported as the core efficacious interventions. Successful outcome has been reported on several of these interventions. But, since most of the literature consists of uncontrolled case reports or small case series, confident conclusions cannot be drawn. This is evidenced by the three randomized trials with adults exploring CBT efficacy. Ninan et al. (2000) found CBT superior to clomipramine and placebo at post-treatment; the same pattern was reported by van Minnen et al. (2003) in their randomized, controlled trial of CBT, fluoxetine, and a wait-list condition. Azrin et al. (1980) found that habit reversal was more effective than negative practice, where subjects were told to act out the motions of hair pulling in front of a mirror, without doing any damage, for 30 seconds every hour, and then to maintain the exercises for 4 days after entirely breaking their habit and finally to gradually decrease the exercises over a 2-week time period. The treatment rationale involves the principles of satiation and heightened awareness. The problem of relapse following CBT has been highlighted in several studies (Lerner et al. 1998, Keuthen et al. 2001, Mouton and Stanley 1996). The limited and equivocal treatment literature suggests that there is neither a universal nor a complete response to any treatment for trichotillomania. Controlled studies of the efficacy of CBT treatments involving habit reversal, pharmacotherapy, and their combination are needed.

**Hypnotherapy**

There are no formal studies of the use of hypnosis for trichotillomania, but there are many published reports of beneficial treatment (Barabasz 1987, Cohen et al. 1999, Fabbri and Dy 1974, Kohen 1996, Rowen 1981, Zalsman et al. 2001). Benefits may be variable. Some patients may have dramatic improvement. For some who improve, the benefits may be short-lived. As with behavioral interventions, the benefits of this approach are sometimes dependent on a highly motivated patient who can regularly carry out self-hypnotic measures as instructed by the psychiatrist. Some patients who have obtained partial benefits from either hypnosis or medication do well when both treatments are combined. Successful use of hypnotherapy for children with trichotillomania has also been reported (Cohen et al. 1999).

**Dynamic Psychotherapy**

Many psychoanalytically oriented descriptions of people with trichotillomania have been published. These reports generally describe the psychodynamic formulations of individual cases and should not be the basis for generalizations about most individuals with trichotillomania. Although patients with trichotillomania may benefit from exploration and attempts to reduce intrapsychic conflict, the literature does not provide persuasive evidence of the efficacy of this approach in reducing hair pulling.

**Self-help and Other Groups**

Self-help groups for patients with trichotillomania have appeared. Some are based in the structure of other 12-step programs. Some patients appear to experience meaningful reduction in hair-pulling symptoms after beginning participation in such a group. Although the efficacy of such groups in reducing symptoms remains to be established, most patients with trichotillomania can benefit from meeting other individuals with similar symptoms. Because of the lack of general awareness of trichotillomania, these individuals frequently believe that they are “oddball” individuals with a behavior that is unique. Many have experienced parental condemnation for the behavior and have been frequently castigated for a “habit” that may be viewed by others as under their voluntary control. The experience of meeting others with the condition is extremely supportive for such individuals and may help to reduce the attendant stress while supporting self-esteem. Where programs specifically oriented toward trichotillomania may not be generally available, these individuals may benefit from groups oriented toward OCD.

**Treatment of Comorbid Conditions**

Depression, dysthymic disorder, and anxiety symptoms occur frequently in patients with trichotillomania. Successful treatment of depression may not be associated with reduction in trichotillomania. If depression or dysthymic disorder is present and independently provides an indication for medication, one of the antidepressants discussed earlier should be
chosen. If fluoxetine is used, the psychiatrist should be aware that a dose that is sufficient for reduction of the depressive symptoms may not be sufficient for reduction of trichotillomania. If panic disorder is present, either medication may still be used, but fluoxetine may initially exacerbate panic attacks in such patients and initiation of treatment at low doses (2.5–5 mg/day) should be considered. With slow titration upward, the patient should generally be able to tolerate usual doses with concomitant amelioration of the panic disorder. Combined treatment with anxiolytics may be useful for some and may contribute to the reduction in symptoms of trichotillomania. Other conditions that may be present, like OCD or eating disorders, may require special attention. Although fluoxetine may be useful for patients with eating disorders, medication treatment alone is unlikely to be adequate and the usual multimodal approaches for the treatment of bulimia nervosa or anorexia are appropriate. OCD may respond to treatment directed at trichotillomania, but adjunctive behavioral treatment of symptoms of OCD may be desirable.

Age- and Cultural-Related Features
When trichotillomania presents in early childhood, as discussed earlier, the condition may be likely to be inherently self-limited. Often, all that may be necessary is to draw the child’s attention to the behavior in some systematic way and to clarify for the child that the behavior is undesirable. Such methods include daily application of a nonmedicinal ointment to the affected region and reminding the child that the purpose is elimination of the hair-pulling habit. Some suggest that the child be given the responsibility of applying the ointment with parental supervision. Others suggest that parents should monitor the child as much as possible and respond with reminders that the hair should not be pulled and rewards with verbal encouragement for ceasing to pull hair. There have been no systematic studies of the benefits of such interventions, but dermatologists who specialize in the treatment of children have noted that hair-pulling behavior may frequently disappear within a few weeks of initiating such an approach. In circumstances in which childhood trichotillomania is more persistent, the parent and psychiatrist are faced with a dilemma. More elaborate behavioral interventions, such as habit reversal, should be tried. This, however, may be difficult with a child. Rosenbaum and Ayllon (1981) have described a modified version of habit reversal that may be employed with children. Hypnosis has been also used in the treatment of habit disorders in children. Medication should be cautiously considered when treating childhood trichotillomania. Although medication may be useful, the absence of data supporting the benefits of such treatments in children indicates a conservative approach. If medication is considered, its use in the treatment of childhood OCD should serve as a guideline.

Should the psychiatrist be presented with trichotillomania in a person of advanced age, special attention should be paid to usual concerns regarding the use of these medications in the elderly. Lower doses of medication should be considered because of potential altered pharmacokinetics in older persons. Medications with anticholinergic side effects (such as clomipramine) may present greater hazards for the older person. Sedative-hypnotic anxiolytics should be used sparingly because of greater vulnerability to cognitive side effects and the increased risk of falling. Women of childbearing potential (perhaps the majority of people who may present for treatment) should be advised regarding the potential risks of these medications to a developing fetus. If the patient is pregnant or considering pregnancy, behavioral treatments may be favored.

Clinicians should be sensitive to the interaction between cultural values and trichotillomania. Women of some cultures may be more prone to distress if trichotillomania is perceived as a hindrance to achieving valued goals, like marriage. Also, in some communities, wigs and other hair accessories are generally acceptable and may present a comfortable means of diminishing the cosmetic impact of hair loss. In other communities, such accoutrements may themselves draw undesired attention.

Refractory Response or Nonresponse to Initial Treatment
Because research in the treatment of trichotillomania is still limited, it is not possible to recommend an initial best treatment for all patients. However, the decision is often determined by available resources. Support groups may not be easily found in many areas. Hypnotherapy and behavioral therapy may be more easily available, but psychiatrists with these skills may not be experienced in the specific techniques used in this condition. Pharmacological interventions may be more readily available. Wherever possible, simultaneous multimodal interventions should be considered. Pharmacological, behavioral, and hypnotic interventions, which may each be only partially useful, may be synergistic when used in combination.

If therapy with a single medication is not successful, the psychiatrist may consider augmenting one agent with another. Augmentation strategies in the treatment of trichotillomania have not been studied. General principles of augmentation used in the treatment of depression or OCD may be considered. There may be particular benefit in combining anxiolytic agents (such as buspirone or clonazepam) with an SSRI antidepressant. As noted above, the advent of atypical neuroleptics may offer a new and possibly efficacious treatment option. Despite the increasing safety of these medications, caution should be used in the introduction of a neuroleptic for the treatment of a persistent condition.

Clinical Vignette 4

Mr. G, a 32-year-old podiatrist, began pulling out hairs in his second year of college. He had always been a generally anxious person and thought of it as a nervous habit. Never particularly concerned about his appearance and noting the familial disposition to male pattern hair loss, he felt resigned to eventual baldness and thought little about it. He noted that his hair pulling tended to be worse in a variety of circumstances: before examinations, after a breakup with a girlfriend, while studying, and while watching television. He thought the last circumstance surprising. The others seemed to be situations of understandable stress, but television relaxed him. Indeed, at those times he was hardly aware of it until he would find his hands roaming searchingly through his scalp and would then find a small pile of hairs beside him on the sofa. Occasionally, an acquaintance would comment—with varying degrees of tact—on the ratty appearance of his hair, particularly

Chapter 80 • Impulse-Control Disorders

Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 Diagnostic Criteria for Research do not include diagnostic criteria for IED. It is included in ICD-10 as an “other habit and Impulse-Control Disorder.” The ICD-10 Diagnostic Criteria for Research and the DSM-IV-TR criteria for kleptomania, pyromania, and trichotillomania are essentially equivalent. Finally, the ICD-10 Diagnostic Criteria for Research for pathological gambling are mono-thetic (i.e., A plus B plus C plus D are required) whereas the DSM-IV-TR criteria set is polythetic (i.e., 5 out of 10 required) with different items. Furthermore, the ICD-10 criteria specify “two or more episodes of gambling over a period of at least 1 year,” whereas DSM-IV-TR does not specify a duration.

**Definition**

The *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) states that the essential feature of AD is the development of clinically significant emotional or behavioral symptoms in response to an identifiable psychosocial stressor (American Psychiatric Association 2000). The symptoms must develop within 3 months after the onset of the stressor (criterion A). The clinical significance of the reaction is indicated either by marked distress that is in excess of what would be expected given the nature of the stressor or by significant impairment in social or occupational (academic) functioning (criterion B). This disorder should not be used if the emotional and cognitive disturbances meet the criteria for another specific Axis I disorder (e.g., a specific anxiety or mood disorder) or are merely an exacerbation of a preexisting Axis I or Axis II disorder (criterion C). AD may be diagnosed if other Axis I or II disorders are present, but do not account for the pattern of symptoms that have occurred in response to the stressor. The diagnosis of AD does not apply when the symptoms represent bereavement (criterion D). By definition, AD must resolve within 6 months of termination of the stressor or its consequences (criterion E). However, the symptoms may persist for a prolonged period (i.e., longer than 6 months) if they occur in response to a chronic stressor (e.g., a chronic, disabling general medical condition) or to a stressor that has enduring consequences (e.g., the financial and emotional difficulties resulting from a divorce) (American Psychiatric Association 2000).

Although the above definition provides a certain structure for identifying and describing AD, there is still uncertainty as to when the impairment in functioning or the severity of the psychiatric symptoms that develop in response to a stressor are sufficient to warrant a diagnosis of AD. The DSM-IV-TR describes the boundary issues between conditions that may be a focus of clinical attention (V codes), subthreshold disorders [not otherwise specified (NOS) disorders], and the specific mental disorders (American Psychiatric Association 2000). A compelling literature documents that there is much “physical” in mental disorders and much “mental” in physical disorders (p. xxx). No definition adequately specifies precise boundaries for the concept of a “mental disorder.” “The concept… lacks a consistent operational definition that covers all situations. …Whatever its original cause, it must currently be considered a manifestation of a behavioral, psychological, or biological dysfunction in the individual” (p. xxxi). The issue of defining boundaries is especially problematic in the subthreshold diagnoses, for example, the AD, in which there are no symptom checklists, algorithms, or guidelines for the “quantification of attributes” (p. xxxii).

AD is a subthreshold diagnosis, which has undergone a major evolution since the original Diagnostic and Statistical Manual of the American Psychiatric Association 1952.

The symptoms of AD are defined in terms of their being a maladaptive response to a psychosocial stressor. There are, in fact, no specific symptoms of AD. The nature of the symptomatology is described by a variety of possible “subtypes” (Appendix 1). Mezzich et al. (1981) and Strain (1981) observed that many of the subtypes of AD were infrequently employed (e.g., “with mixed emotional features”), whereas “with physical complaints,” a DSM-III-R category had insufficient time to be observed (American Psychiatric Association 1987). Both were deleted in DSM-IV-TR. The lack of specific symptoms or quantifiable criteria of the AD permits the labeling of early or temporary mental states when the clinical picture is vague, and it does not meet full evidence for a specific mental disorder, but the morbid state is more than expected in a normal reaction, and treatment or an intervention may be indicated. ADs are an essential “linchpin” in the psychiatric–taxonomic spectrum-hierarchy: (1) disorders with specific diagnostic criteria; (2) disorders NOS; (3) ADs; (4) other conditions that may be a focus of clinical attention (V codes) (American Psychiatric Association 2000); and (5) normal fluctuations of mental states. Demoralization has been suggested as another V-code.
category and should be distinguished from AD and other pathological conditions (Slavney 1999). Understandably, the ADs are a diagnostic group with a significant evolution since 1952 (Table 81–1). As the diagnosis of AD has evolved, the recognition of other stress-related disorders, for example, posttraumatic stress disorder (PTSD) has occurred. A new acute stress disorder diagnosis—those stress reactions that follow a disaster or cataclysmic personal event (e.g., acute stress disorder) (Spiegel 1994)—was introduced into DSM-IV-TR.

Disorders that do not fulfill the criteria for a specific mental disorder may be accorded a lesser interest by mental health care workers, research institutes, and third-party payers, even though they present with serious (or incipient) symptoms that require intervention or treatment. Given this

**Acute:** This specifier can be used to indicate persistence of symptoms for less than 6 mo.

**Chronic:** This specifier can be used to indicate persistence of symptoms for 6 mo or longer. By definition, symptoms cannot persist for more than 6 mo after the termination of the stressor or its consequences. The chronic specifier therefore applies when the duration of the disturbance is longer than 6 mo in response to a chronic stressor or a stressor that has enduring consequences.

---

concept, the ADs are formulated as a means of classifying psychiatric morbidity that is clinically significant; when the symptom profile is as yet insufficient to meet the more specifically operationalized criteria for another mental disorder; when the symptoms, disturbance of mood, and vocational or interpersonal dysfunction are in excess of a normal reaction to the stressors in question; and for which treatment is indicated. For example, a diagnosis of AD is not given when the clinical picture is a psychosocial problem (V code) requiring clinical attention, such as noncompliance, phase of life problem, bereavement, or occupational (academic) problem. Their etiological and dynamic attributes make the AD a fascinating group of disorders that serve as a fulcrum between normality and more specific mental disorders (Figure 81–1).

Attention to less severe mental symptoms (and psychiatric morbidity) may forestall the evolution to more serious disorders and allow remediation before relationships, work, and functioning are so impaired that they are disrupted or permanently sundered. Yet, in the gray area in which early diagnosis may have enormous value with modest therapeutic investment, guidelines are the most tenuous. It is the diagnosis may have enormous value with modest therapeutic investment, guidelines are the most tenuous. It is the professionals at the “front door”—primary care physicians, triage personnel, emergency department staff, walk-in clinic staff—who need assistance in making this difficult call: Is there sufficient psychiatric morbidity to warrant mental health intervention?

Problems with the use of the AD diagnosis in clinical practice were highlighted in a survey of child and adolescent psychiatrists. Of those who responded, 55% indicated that they used AD to avoid the stigmatization of patients (in this case children and youth). More of those who favored the use of this category were psychodynamically oriented, not formally trained in the DSM-III-R, and not inclined to use NOS categories (American Psychiatric Association 1987, Setterberg et al. 1991). More than half of these psychiatrists did not consider the temporal onset criterion or the exclusionary criteria in applying this diagnosis. The survey results suggested that some psychiatrists, in part to protect their patients from the feared adversities of major psychiatric nomenclature, use the AD diagnosis excessively and incorrectly. Interestingly, the less stigmatizing nature of the condition when evaluating patients’ risks (Katzman and Tamori 2005).

It is equally likely that the lack of specificity characterizing the AD diagnoses, make it difficult to truly separate them from other psychiatric syndromes. In a recent study, Casey et al. (2006) examined variables that might distinguish AD from other depressive episodes. The patients were screened for depression severity with the Beck Depression Inventory (BDI) and then interviewed with the Schedule for Clinical Assessment in Neuropsychiatry (SCAN) which includes questions assessing the presence of AD. The authors were unable to find any independent variables that distinguished AD from other depressive episodes, including the severity of the BDI score at the outset.

Because AD is a nonpejorative psychiatric condition (Kovacs et al. 1993), it may also be overdiagnosed in youths (Kovacs et al. 1994). Andreasen and Wasek (1980) observed that 25% of a sample of adolescents with AD had attempted suicide and that 17% probably “would have met DSM-III criteria for major depressive disorder” because they had the required symptoms. Kovacs et al. (1993) stated, “Suicide attempts among clinically referred youths occur mostly in the context of specific psychiatric disorders, including major depressive and dysthymic disorders, and rarely in the context of AD, further suggesting that AD may have been incorrectly diagnosed in some cases.” Reports that 5–12% of young inpatients with psychiatric disorders have been assigned a diagnosis of AD also raise the possibility of mislabeling (Andreasen and Wasek 1980, Faulstich et al. 1986). Nevertheless, in psychological autopsy studies of adolescent suicide completers, approximately 20% do not meet the criteria for any single psychiatric diagnosis, although they present with significant functional impairment and life-threatening behavior.

The problem of how to diagnose individuals with suicidal behavior who do not meet the criteria for a specific mental disorder has received considerable recent attention. De Leo et al. (1986aa, 1986bb) reported on the association of AD and suicidality. Runeson et al. (1996) observed from psychological autopsy methods that there was a very short median interval between first suicidal communication and suicide in AD (less than 1 month) compared to major depressive disorder (3 months), borderline personality disorder (30 months), or schizophrenia (47 months).

Recent life events, which would constitute an acute stress, were commonly found to correlate with suicidal behavior in a group that included those with AD (Isometsa et al. 1996). Spalletta et al. (1996) observed that assessment of suicidal behavior to be an important tool in differentiating major depressive disorder, dysthymic disorder, and AD. Furthermore, AD patients were observed to be among the most common recipients of a deliberate self-harm (DSH) diagnosis, with the majority involving self-poisoning (Vlachos et al. 1994). Thus, DSH with all its variants, for

![Figure 81–1](image_url) Descending order of depressive states, from most serious to least depressed mood, as a state of being for an occurrence of the moment.
example, reckless driving, is more common in AD patients (Vlachos et al. 1994), whereas the percentage of completed suicidal behavior per se was found to be higher in depressed patients (Spalletta et al. 1996). Of note, biological findings in suicidal patients with AD suggest characteristic patterns of monoamine oxidase (MAO) and noradrenaline turnover (Tripodianakis et al. 2000). Clearly, what is regarded, as a subthreshold diagnosis—AD—does not necessarily imply the presence of subthreshold symptomatology.

**Epidemiology**

AD has principally been studied in clinical samples. Epidemiological data in adults are not available. The AD diagnosis was not included in the Epidemiologic Catchment Area Study conducted in five disparate sites throughout the United States, and there are only a few studies in children and adolescents. Andreasen and Wasek (1980) reported that 5% of an inpatient and outpatient sample were labeled AD. Fabrega et al. (1987) observed that 2.3% of a sample of patients presenting to a walk-in diagnostic and evaluation center clinic met criteria for AD with no other Axis I or Axis II diagnoses. When patients with other Axis I diagnoses (Axis I comorbidities) were also included, 20% had the diagnosis of AD. In a sample of more than 11,000 patients (all ages) 10% were found to have AD (Table 81–2), making it the second largest diagnostic category (Fabrega et al. 1986, 1987, Mezzich et al. 1989). In the Pittsburgh sample studied, 16% of the children and adolescents younger than 18 years were diagnosed with AD (Fabrega et al. 1986). In adults, women predominated over men by approximately 2:1. The sex ratio was more equal in children and adolescents, although there was still a slight excess of female patients.

Prevalence estimates of AD in other clinical populations have been characterized by considerable variability (see Table 81–2). In general, hospital inpatient and psychiatric consultation populations, AD was diagnosed in 21.5% and 11.5%, respectively (Popkin et al. 1988, Snyder and Strain 1990). Strain et al. (1998b) examined the consultation–liaison data from seven university teaching hospitals in the United States, Canada, and Australia. The sites had all used a common clinical database to examine 1,039 consecutive referrals. AD was diagnosed in 125 patients (12.0%), as the sole diagnosis in 81 (7.8%), and comorbidly with other Axis I and II diagnoses in 44 (4.2%) (Strain et al. 1998a). It had been considered as a “rule-out” diagnosis in an additional 110 (10.6%). AD with depressed mood, anxious mood, or mixed emotions were the most common subcategories used. AD was diagnosed comorbidly most frequently with personality disorder and organic mental disorder. Sixty-seven patients (6.4%) were assigned a V-code diagnosis only. Patients with AD compared to other diagnostic categories were referred significantly more often for problems of anxiety, coping, and depression; had less past psychiatric illness; and were rated as functioning better—all consistent with the construct of AD as a maladaptation to a psychosocial stressor. Interventions employed for this general hospital inpatient cohort were similar to those for other Axis I and II diagnoses, in particular, the prescription of antidepressant medications. Patients with AD required a similar amount of clinical time and resident supervision.

Oxman et al. (1994) observed that 50.7% of elderly patients (aged 55+ years) receiving elective surgery for coronary artery disease developed AD related to the stress of surgery. Thirty percent had symptomatic and functional impairment 6 months following surgery. It is reported that 27% of elderly patients examined 5–9 days following a cerebral vascular accident had symptoms that fulfilled the criteria for AD (Kellermann et al. 1999). Spiegel (1996) observed that half of all cancer patients have a psychiatric disorder, usually an AD with depression. Since patients treated for their mental states had longer survival time, treatment of depression in cancer patients should be considered integral to their medical treatment. AD is a frequently made diagnosis in patients with head and neck surgery (16.8%) (Kugaya et al. 2000), patients with HIV dementia (73%) (Pozzi et al. 1999), cancer patients from a multicenter survey of consultation–liaison psychiatry in oncology (27%) (Grassi et al. 2000), dermatology patients (29% of the 9% who had psychiatric diagnosis) (Pulimood et al. 1996), and

*CGAS, Children's Global Assessment Scale.
suicide attempters (22%) examined in an emergency room (Sawadogo and Valach 1997). Other studies include diagnosis of AD in more than 60% of inpatients being treated for severe burns (Perez-Jimenez et al. 1994), 20% of patients in early stages of multiple sclerosis (Sullivan et al. 1995), and 40% of poststroke patients (Shima et al. 1994).

In a study of emergency department visits, it was reported that 13% of adults and 42% of adolescents were diagnosed with AD (Hillard et al. 1987). Among adolescents in that study, AD was twice as common as any other diagnosis, including substance abuse. Faulstich et al. (1986) reported the prevalence of DSM-III conduct disorder and AD for adolescent psychiatric inpatients. Mezzich et al. (1981) and Fabrega et al. (1987) evaluated walk-in clinic patients (mainly adults) for the current presence of 64 symptoms in three diagnostic cohorts: (1) specific diagnoses, (2) AD, and (3) “not ill.” Vegetative, substance use or abuse, and characterological symptoms were greatest in specific diagnoses, intermediate with the AD, and least in the “not ill.” The symptoms of mood and affect, general appearance, behavior, disturbance in speech and thought pattern, and cognitive functioning had a similar distribution (specific diagnosis > AD > “not ill”). The patients with AD were significantly different from the “not ill” group with regard to more “depressed mood” and “low self-esteem” (P < 0.0001). The patients with AD and the “not ill” group had minimal disturbance of thought content and perception. Twenty-nine percent of the patients with AD versus 9.0% of the “not ill” patients had a positive response on the suicide indicators. The three cohorts did not differ on the kinds or amounts of general medical conditions.

Andreasen and Wasek (1980), using a chart review, reported that more inpatient adolescents experienced acting-out and behavioral symptoms than adults who were observed to have significant depressive symptoms (87.2% and 63.8%, respectively). Anxiety symptoms were frequent at all ages. They also observed that in their AD cohorts, 21.6% of the adolescents and 11.8% of the adults’ fathers had problems with alcohol.

There are two published epidemiological studies in populations of children and adolescents that included AD. One, conducted in Puerto Rico, employed a two-stage screening process using standardized rating scales as well as structured and unstructured clinical interviews (Bird et al. 1988, 1989). The prevalence rate of AD was determined to be 7.6% if an upper limit of 70 on the Children’s Global Assessment Scale (CGAS) is applied (Shaffer et al. 1983). However, if an upper limit of 60 is imposed (corresponding to “moderate” impairment on the CGAS), the prevalence of AD dropped to 4.2%. This indicates that up to 40% of AD diagnosed patients have only mild impairment, more than for any other diagnosis. A recent study conducted in a very large birth registry in Finland found that AD with mixed disturbance of emotions and conduct was the most frequent AD diagnosis, and occurred in 3.4% of the population at the time of the assessment (Almqist et al. 1999). Other studies conducted in pediatric patients who presented with psychiatric disturbance from four different clinics indicated rates of AD across the clinics ranging from 25 to 65% (Jacobson et al. 1980). The prevalence of AD in children and adolescents may be somewhat higher than it is in adults, but varies considerably according to the population studied.

The relationship between family functioning and AD was evaluated by administering the Family Assessment Devise (FAD) to families who had a member with one of seven mental disorders: schizophrenia, bipolar disorder, major depression, anxiety disorder, eating disorder, substance abuse, and AD (Friedmann et al. 1997). Regardless of which specific psychiatric diagnosis was present in the family member, having a family member in an acute phase of any of these psychiatric disorders—even a subthreshold diagnosis such as AD, was a risk factor for poor family functioning. AD in a family member was a significant family stressor.

**Etiology**

By definition, the ADs are stress-related phenomena in which a psychosocial stressor results in the development of maladaptive states and psychiatric symptoms. The condition is presumed to be time limited, that is, a transitory reaction; symptoms recede when the stressor is removed or a new state of adaptation is defined. There are also other stress-related disorders in DSM-IV-TR, such as PTSD and acute stress disorder those stress reactions that follow a disaster or cataclysmic personal event (American Psychiatric Association 2000). These stress disorders are among the few conditions DSM-IV-TR, along with substance-induced disorders and mental disorders due to a general medical condition, with a known cause and for which the etiological agent is essential to establishing the diagnosis. For the most part, the DSM-IV-TR is relatively atheoretical with regard to etiology and is instead phenomenologically driven in its definitions of disorders (Feighner et al. 1972). However, the DSM-IV-TR stress-induced disorders, including the AD, require the diagnostician to impute etiological significance to a life event—a stressor—and relate its effect in clinical terms to the patient, his/her symptoms, and his/her behavior.

That the relationship between stress and the occurrence of a psychiatric disorder is both complex and uncertain has caused many to question the theoretical basis of AD (Holmes and Rahe 1967, Rutter 1981, Weiner and Del Gaudio 1976). The linear model of stress–disease interaction, which serves as the model for AD has been questioned (Paykel et al. 1971, Woolston 1988). The linear model presupposes that a direct and clearly identifiable pathological reaction may follow a stressful event, a scenario that no doubt occurs in some individuals with AD but may not accurately characterize others. For example, there may be multiple stressors, insidious or chronic, as opposed to discrete events. Furthermore, relatively minor precipitating events may generate a disturbance in an individual who has previously been sensitized to stress.

Several authors have criticized the stressor criterion in AD because stressors are difficult to specify and measure, and their clinical implications and impact are uncertain (Fabrega and Mezzich 1987). Questions pertain to whether patients with AD are unusually sensitive to psychosocial events not likely to cause disturbance in others. Are there individuals who have been exposed to high levels of stress, the severity or accumulation of which would probably produce negative consequences in most people?

Diverse variables and modifiers are involved in the presentation of AD after exposure to a stress. Cohen (1981) argued that acute stresses are different from chronic ones in both psychological and physiological terms; that the meaning...
of the stress is affected by “modifiers”—ego strengths, support systems, and prior mastery—and that one must differentiatemanifest and latent meaning of the stressors (e.g., loss of a job may be a relief or a catastrophe). An objectively overwhelming stress could have little impact on one individual, whereas another individual could regard a minor one as cataclysmic. A recent minor stress superimposed on a previous underlying (major) stress (which had no observable effect on its own) may have a significant impact, not operating independently but by its additive effect—the concatenation of events (Hamburg, personal communication).

Proper use of the AD diagnosis also requires a careful understanding of the timing of the stressor and the subsequent emotional or behavioral symptoms; by definition, this must occur within 3 months of the stressor. Until DSM-IV-TR, a time limit was also imposed regarding how long after the occurrence of the stressor this diagnosis could be employed. Before DSM-IV-TR, AD was a “transitory” diagnosis that, by definition, could not exceed 6 months; after 6 months, the diagnosis had to be changed to another psychiatric disorder. However, there are limited data with regard to the timing of symptoms following the occurrence of the stressor. Depue and Monroe (1986) and Rahe (1990) stated that the model of a single stressor impinging on an undisturbed individual to cause symptoms at a single point in time is insufficient to account for the many presentations of stress and illness in the clinical situation. Holmes and Rahe (1967) assigned relative values to specific stressors. Other life events scales have also been shown to be inconsistent in their ability to link stress and illness (Dohrenwend et al. 1978, Paykel et al. 1971, Tennant 1983). Depue and Monroe (1986) and Skodol et al. (1990) identified significant methodological problems in evaluating the quality, quantity, and timing of both stressors and symptoms. It was difficult to establish interrater reliability with regard to these three entities of a stressor. With regard to another attempt to assess and document stress in a multiaxial diagnostic schema, Axis IV of DSM-III, and DSM-III-R, was designed to allow the mental health worker to quantify the stress as a diagnostic attribute. Unfortunately, this measure was confounded by low reliability (Rey et al. 1988, Spitzer and Forman 1979, Zimmerman et al. 1987). As a result, the DSM-IV-TR Axis IV is now a qualitative list of psychosocial–circumstantial problems.

Andreasen and Wasek (1980) described the differences between the types of stressors found in adolescents and those of adults; respectively, 59 and 35% of the precipitants had been present for a year or more, and 9 and 39% for 3 months or less. Fabrega et al. (1987) reported that their group of patients with AD described stressors compared with the other cohorts: “specific psychiatric diagnoses” and “patients not ill.” There was a significant difference in the amount of stressors reported relevant to the clinical request for evaluation; the group with AD, compared with the “specific diagnoses” and “not ill” patients, were overrepresented in the “higher stress” categories. Popkin et al. (1988) reported that in their general hospital inpatient consultation cohort, 68.6% of the patients were judged to have their medical illness as the primary psychosocial stressor. Snyder and Strain (1990) observed that the assessment of stressors on Axis IV was significantly more severe ($P = 0.0001$) for inpatient psychiatric consultation patients with AD compared with patients with other diagnostic disorders.

**Chapter 81 • Adjustment Disorders**

**Diagnosis and Differential Diagnosis**

Each of the diagnostic constructs required for the diagnosis of AD is difficult to assess and measure: (1) the stressor, (2) the maladaptive reaction to the stressor, and (3) the time and relationship between the stressor and the psychological response. None of these three components has been operationalized for a diagnostic decision tree, which consequently plagues the AD diagnosis with limited reliability.

In contrast to other DSM-IV-TR disorders, the diagnostic criteria for AD include no clear and specific symptoms (or checklist) that collectively compose a psychiatric (medical) syndrome or disorder.

First, with regard to the maladaptive reaction, it is unclear how this concept can or should be operationalized. The social, vocational, and relationship dysfunctions, which are unspecified qualitatively or quantitatively, do not lend themselves to reliable or to valid assessment. The elements of culture (i.e., the expectable reactions within a specific cultural environment), differences in gender responses, developmental level differences, and differences in the “meaning” of events and reactions to them by a specific individual further confound it. Powell and Mccone (2004) make this point in their case report of the treatment of a patient with AD secondary to the September 11th terrorist attacks. Since there has never before been a large-scale terrorist attack in America, how are clinicians to know what a “normal” response to such an event would be?

The concepts of “average expectable environment” (e.g., the expectation of adequate food in a household in an industrial society) and “patient’s explanatory belief model” are examples of an attempt to weigh cultural and subjective differences in the assessment of an individual’s mental state and reaction (Hartmann 1986, Klineman 1980). Such individual cultural–social considerations often require an understanding on the part of the psychiatrist and thereby often render the assessment of whether a reaction is excessive or maladaptive a judgment call.

Mixed anxiety–depressive disorder is another subthreshold diagnosis that is included as an unofficial category in the appendix of research criteria needing further study in DSM-IV-TR. This research category is similar to AD with mixed anxiety and depression that does not meet criteria for a specific mood or anxiety disorder, thus making it difficult to draw a boundary between the two disorders except that there is less emphasis on a stressor as a precipitating cause in the non-AD category. Furthermore, using the DSM-III-R definition of AD which limited the duration to 6 months, the main difference between the two diagnoses was the chronicity of the mixed anxiety–depressive disorder, as was noted in the mixed anxiety–depression field trial (Zinbarg et al. 1994). Now, with the change in criterion C for AD allowing for chronic forms of AD, the problem of differentiating the two subthreshold diagnoses remains difficult. This uncertainty is further complicated by the question of treatment. Is this an anxiety accompanied by depression that should be treated with anxiolytics, such as benzodiazepines or is this a depression accompanied by anxiety that should be treated with an antidepressant, such as a selective serotonin reuptake inhibitor (SSRI)?

The criterion and predictive validity of the diagnosis of AD in 92 children who had new onset insulin-dependent diabetes mellitus were examined (Kovacs et al. 1995). DSM-III
criteria were employed plus requiring four clinically significant signs or symptoms, and the time frame extended to 6 months (instead of the 3 months specified in the definition) after the diagnosis of diabetes. Thirty-three percent of the cohort developed AD (mean 29 days after the medical diagnosis) and the average episode length was 3 months with a recovery rate of 100%. The five-year cumulative probability of a new psychiatric disorder was 0.48 in comparison to 0.16 for the non-AD subjects. The findings support the criterion validity of the AD diagnosis using the criterion of predicting the future development of a psychiatric disorder.

**Maladaptation**

Although the diagnosis of AD requires evidence of maladaptation, it is notable that no specific requirement for functional impairment has been included (e.g., there is no requirement for a certain decrement in the Global Assessment of Functioning Scale score in order to make the diagnosis). Fabrega et al. (1986) stated that both subjective symptoms and decrement in social function can be considered maladaptive and that the severity of either of these is subject to great individual variation. However, they could not conclude that the level of severity of psychiatric illness observed correlates with impaired functioning in three areas: occupational status, family, or with other individuals.

The psychiatrist needs to examine the patient’s behavior to see whether it is beyond what is expected in a particular situation, and for that patient. In order to do this, the psychiatrist needs to take into account the patient’s cultural beliefs and practices, his or her developmental age, and the transient nature of the behavior. If the behavior lasts a few moments or is an impulsive outburst, it would not qualify for a maladaptive response to justify the diagnosis of AD. The behavior in question should be maladaptive for that patient, in his/her culture, and sufficiently persistent to qualify for the maladaptation requirement for the AD diagnosis.

**Stresses**

No criteria or guidelines are offered in DSM-IV-TR to quantify the degree of stress required for the diagnosis of AD or assess its effect or meaning for a particular individual at a given time. Many of the statements regarding the problem of assessing maladaptation described above apply equally well to the assessment of stressors (Woolston 1988, Zilberg et al. 1982). Mezzich et al. (1981) attempted to classify and quantify the psychosocial stressors in 13 domains (i.e., health, bereavement, love and marriage, parental, family stressors for children and adolescents, other familial relationships, work, school, financial, legal, housing, and miscellaneous). The measurement of the severity of the stressor and its temporal and causal relationship to demonstrable symptoms are often unclear.

According to DSM-IV-TR, even if a specific and presumably causal stressor is identified, if enough symptoms develop so that diagnostic criteria are met for a specific disorder, then that diagnosis should be employed instead of a diagnosis of AD (American Psychiatric Association 1980, 1987, 2000). Therefore, the presence of stressors does not automatically signify a diagnosis of AD, and conversely, a diagnosis of a specific disorder (e.g., major depressive or anxiety disorder) does not imply the absence of concomitant or concurrent stressful events (Setterberg et al. 1991).

The modifications introduced in DSM-IV-TR, which differentiate between acute and chronic forms of AD, solved the problem of a 6-month limitation in DSM-III-R’s criteria. This change was validated by Despland et al. (1995), who observed that 16% of patients with AD required treatment for longer than 1 year, with the mean length exceeding the prior limitation of 6 months.

**Assessment of the Subtypes of Adjustment Disorder, Comorbidity, and Diagnostic Boundaries**

The diagnostic criteria for AD define the contextual and temporal characteristics of a subthreshold response to a psychosocial stressor; while the specific quality and nature of the resultant psychological morbidity have been used as a means of subtyping.

DSM-IV-TR identifies six AD subtypes; two of the subtypes define discrete disturbances of mood (e.g., depressed, anxious); two describe mixed clinical presentations (e.g., mixed emotional features, mixed disturbance of emotions and conduct); one specifies disturbance of conduct; and the final subtype, unspecified, is a residual category.

Significant occurrence of comorbidity has been reported in studies of AD using structured diagnostic instruments. In a cohort of children, adolescents, and adults, approximately 70% of AD patients had at least one additional Axis I diagnosis (Fabrega et al. 1987). In the study of correlates of depressive disorders in children, 45% of those with AD with depressed mood had another disorder (Kovacs et al. 1984). However, comorbidity in AD was less than in dysthymic disorder or major depressive disorder, suggesting a “purer” or more encapsulated disturbance in AD.

Several studies reported an association of suicidal behavior in adolescents and young adults with AD. One study found that 56% of those hospitalized for suicidal behavior in an urban hospital setting met the DSM-II criteria for transient situational disturbance (an earlier diagnostic label for what came to be called AD) (Minnaar et al. 1980). A retrospective review of 325 consecutive hospital admissions for deliberate self-poisoning revealed that 58% of all cases met criteria for AD with depressed mood, the majority of whom were female patients aged 15–24 years (McGrath 1989). In a Scandinavian sample of 58 consecutive suicide victims aged 15–29 years, 14% were classified as AD with depressed mood (Runeson 1989); in a US population, 9% of suicide victims aged 10–29 years were reported to have AD (Fowler et al. 1986). These studies underscore the seriousness of AD in a subset of individuals and suggest that although the diagnosis may be subthreshold, its morbidity can be serious and at times even fatal.

The issue of boundaries between the specific mood and anxiety disorders, depressive disorder or anxiety disorder NOS, and the AD remains problematic. The specific mood and anxiety disorders are often associated with and, even precipitated by stress. Therefore, it is not always possible to say one group of diagnoses is accompanied by stress (the AD) and another (e.g., major depressive disorder) is not. Stress may accompany many of the psychiatric diagnoses, but it is not an essential etiological component required to make certain diagnoses (e.g., major depressive disorder).

More research is needed to carefully demarcate the boundaries among the problem-level, subthreshold, and
threshold disorders, in particular with regard to whether subthreshold disorders are etiological precipitants, concomitants, or factors essentially unrelated to the occurrence of a particular psychiatric diagnosis. Furthermore, serial and ongoing observation of the clinical course is required to ascertain whether the AD is a transitory remitting event, the protracted state of a more serious and developing disorder, or an intermittent chronic state of a low-level mood disorder. There is considerable evidence indicating that major depressive disorder is a highly recurrent, often chronic condition that is frequently associated with low-grade symptoms prior to, and between, major episodes (Keller et al. 1995). Thus, the differential diagnoses of depressed mood must be linked to ongoing assessment, not cross-sectional evaluation, which is so often the case; it is essential to maintain a longitudinal view of the subthreshold disorders to know their place in an individual’s affective history. Keller et al. (1995) described the need for a longitudinal taxonomy, a “course-based classification system.”

Boundary issues with subthreshold (i.e., so-called “minor”) disorders of mood and anxiety were studied in the DSM-IV Field Trial for mixed anxiety and depression. Zinbarg et al. (1994) and Liebowitz (1993) reported that subsyndromal disorders were common and could be differentiated from other anxiety disorders. The “subdefinitional threshold” cases were often recurrent or chronic (of more than 6 months’ duration) and thereby, according to DSM-III-R criteria used in the field trial, would not have been labeled AD. However, in DSM-IV-TR, AD can now also have a chronic form that persists longer than 6 months, so that the duration criterion does not help differentiate the subthreshold disorders, anxiety or depressive disorder NOS, and AD. Angst and Ernst (1993) argued that most diagnostic subgroups of depression are artificial and not diagnostic entities, but subtypes of the same spectrum disorder.

These data suggest that AD could be placed in an innovative category of “stress response syndromes,” or for that matter, in several diverse locations within the DSM classification (Strain et al. 1993). However, evidence-based medicine does not offer data to support such alternative groupings at this time. In the extreme, AD could be eliminated altogether, with the advantage of maintaining the atheoretical approach of the DSM conceptual framework. This solution, however, does not seem warranted in view of the findings that demonstrate AD to be a valid diagnosis (Kovacs et al. 1994, 1995).

Construct validity was also observed in a retrospective data study comparing outpatients with single episode major depressive disorder, recurrent major depressive disorder, dysthymic disorder, depressive disorder NOS, and AD with depressed mood with or without mixed anxiety (Jones et al. 1999). The Medical Outcomes Study 36-item Short Form Health Status Survey (SF-36) was completed before and 6 months after treatment. The diagnostic categories were significantly different at baseline, but did not differ with regard to outcome at follow-up. Females were significantly more likely to be diagnosed with major depressive disorder or dysthymic disorder than with AD. Females were also more likely to score lower on the Mental Component Summary scales of the SF-36 scales at admission. AD patients scored higher on all SF-36 scales, as did the other diagnostic groups at baseline and again at follow-up. There was no significant difference among diagnostic groups with regard to treatment outcome. The authors concluded that the results support the construct validity of the AD diagnostic category (Jones et al. 1999).

In reviewing the diagnosis of AD for DSM-IV-TR, one issue emerges as fundamental: the effect of the imprecision of this diagnosis on reliability and validity, because of the lack of behavioral or operational criteria, must be determined. One study (Aoki et al. 1995), however, found three psychological tests, Zung’s Self-Rating Anxiety Scale (Zung 1971), Zung’s Self-Rating Depression Scale (Zung 1965), and Profile of Mood States (McNair et al. 1971), to be useful tools for AD diagnosis among physical rehabilitation patients. Although Aoki et al. (1995) succeeded in reliably differentiating patients with AD from healthy patients, they did not distinguish them from patients with major depression or PTSD.

In a recent study, Grassi et al. (2000) investigated psychosomatic symptoms in patients with AD in a hospital setting in order to further characterize the diagnosis of AD in the medically ill.

Results showed a considerable overlap between AD and abnormal illness behavior including health anxiety, somatization, conversion symptoms, and demoralization among others. Only 13 out of 100 AD patients interviewed did not present with psychosomatic symptoms.

**Course and Natural History**

Andreasen and Hoenk (1982) demonstrated at a 5-year follow-up that there were important differences in adolescents and adults with regard to prognosis. It would be important to extend this long-term observation to cohorts of the elderly and the “old elderlies” (those older than 75 years). Although the prognosis was favorable and most adult patients with AD were symptom free at 5 years (71% were completely well, 8% had an intervening problem, and 21% had a major depressive disorder or alcoholism), adolescents had a far different outcome. At a 5-year follow-up, 43% had a major psychiatric disorder (e.g., schizophrenia, schizoaffective disorder, major depressive disorder, substance abuse disorder, and personality disorder); 13% had an intervening psychiatric illness; and 44% had no psychiatric diagnosis (Andreasen and Hoenk 1982). In adolescents, behavioral symptoms and the chronicity of the morbidity were the major predictors for psychopathological disorders at the 5-year follow-up. This was not so with the adults in the study, and raises the question of whether these adolescents were diagnosed as having AD as part of a prodrome of another more serious disorder.

Kovacs et al. (1994) reported a much different set of findings. The authors report that children who were older at the time of onset of AD recovered faster, and there was a trend for subjects with the depressed mood subtype to recover faster than subjects with other symptoms. The researchers concluded that among young, school-aged, clinic-based patients, AD has clinical information value, and is associated with a favorable short-term prognosis, but is often associated with comorbid psychiatric disorders which complicates assessment. When effects of comorbidity were controlled for, there was no compelling evidence for a negative long-term prognosis during a follow-up period of 7–8 years specifically attributable to the earlier AD (Andreasen...
of ability to function or contain emotions. The AD must include (1) acute hospitalization, (2) uncertain medical diagnosis, (3) pain, (4) medications, (5) separation, and (6) lack of a社交媒体 disorder or the AD diagnosis is significantly altered at discharge. It remains to be seen if either the major depressive disorder were reclassified to AD and the control subjects, similar rates of dysfunction were detected during the follow-up, probably attributable to the specific psychiatric conditions that were present initially.

Snyder and Strain (1989) observed that in the acute care inpatient hospital setting, many of the psychiatric consultation patients initially thought to have an AD did not maintain that diagnosis at the time of discharge. These same authors also observed that many patients initially diagnosed as having major depressive disorder were reclassified to AD at discharge. It remains to be seen if either the major depressive disorder or the AD diagnosis is significantly altered at a 6-week follow-up and, in particular, when the patient has left the hospital. This evolution of psychiatric morbidity within the acute care general medical setting cautions the psychiatrist to go slowly with treatment until there is a level of certainty to justify an intervention, in particular, with a chemotherapeutic modality.

Attempting to diagnose disorders in an early state or before there is a full-blown syndrome or disorder often means that a patient will qualify for the AD criteria or the subsyndromal condition. Just as it is difficult to know when a patient has crossed the diagnostic line (threshold) from normal to disturbed behavior, it is difficult to know how quickly the symptoms will remit with a remission of the stressor, which for the general medical–surgical inpatient include (1) acute hospitalization, (2) uncertain medical diagnosis, (3) pain, (4) medications, (5) separation, and (6) lack of ability to function or contain emotions. The AD must be looked at as a transitory state for most patients, in that it may subside, respond with treatment, evolve to another diagnosis, or be maintained as the stressor continues.

Although most studies do point to a more benign prognosis for the AD, it is important to realize that the risk of serious morbidity and mortality still exists. Several recent studies investigating the association between suicide and AD underscore the importance of monitoring patients closely for suicidality, especially in younger populations. Portzky et al. (2005) conducted psychological autopsies on adolescents with AD who had committed suicide and found that suicidal thinking in these patients was brief and evolved rapidly and without warning. A slightly different profile was found in two other studies that looked at suicide attempters with a diagnosis of AD. These patients were more likely to have poor overall psychosocial functioning, prior psychiatric treatment, personality disorders, substance abuse histories, and a current “mixed” symptom profile of depressed mood and behavioral disturbances (Kryzhunovskaya and Canterbury 2001, Pelkonen et al. 2005). A study of the neurochemical variables of AD patients of all ages who had attempted suicide revealed biologic correlates consistent with the more major psychiatric disorders. Attempters were found to have lower platelet MAO activity, higher MHPG activity, and higher cortisol levels than controls. Though these finding differ from the lower MHPG and cortisol levels found in patients with major depression and suicidality, they are similar to findings in other major stress-related conditions (Tripodianakis et al. 2000).

Treatment

There are few reported randomized controlled trials regarding the psychological, social, or pharmacological treatment of AD (Adams and Gelder 1994, Chalmers et al. 1992, Conte and Karasu 1992). In lieu of any substantive randomized controlled trials to guide treatment, the choice of intervention remains a clinical decision. The Institute of Medicine has developed Guidelines for Clinical Practice: From Development to Use (Field and Lohr 1992). A critical attribute of a guideline is the strength of the evidence. “Practice guidelines should be accompanied by descriptions of the strength of the evidence and the expert judgment behind them. [They] should be accompanied by estimates of the health and cost outcomes expected from the interventions in question, compared with alternative practice” (Field and Lohr 1992, p. 8). Therefore, with no evidence from randomized controlled trials, the treatment recommendations for the AD remain based on consensus rather than evidence. However, there has not been an official consensus conference on the optimal way to treat this disorder. Recommendations of clinical experts may differ from the results of meta-analyses of randomized controlled trials (Antman et al. 1992).

There are two clinical empirical approaches to treatment. One is based on the understanding that this disorder emanates from a psychological reaction to a stressor. The stressor needs to be identified, described, and shared with the patient; plans must be made to mitigate it, if possible. The abnormal response may be attenuated if the stressor can be eliminated or reduced. Popkin et al. (1990) have shown that in the medically ill, the most common stressor is the medical illness itself; and the AD may remit when the medical illness improves or a new level of adaptation is reached. The other approach to treatment is to provide intervention for the symptomatic presentation, despite the fact that it does not reach threshold level for a specific disorder, on the premise that it is associated with impairment and that treatments that are effective for more pronounced presentations of similar pathology are likely to be effective. This may include psychotherapy, pharmacotherapy, or a combination of the two (Schatzberg 1990).

Psychotherapy

A psychotherapeutic intervention in AD is intended to reduce the effects of the stressor, enhance coping with the stressor that cannot be reduced or removed, and establishing a mental state and support system to maximize adaptation. Psychotherapy can involve any one of several approaches:
cognitive-behavioral treatment, interpersonal therapy, psychodynamic efforts, or counseling. Though brief therapeutic interventions are usually all that are needed, ongoing stressors or enduring character pathology that may make a patient vulnerable to stress intolerance may signal the need for lengthier treatments (Katzman and Tomori 2005).

The first goal of psychotherapy is to analyze the nature of the stressors affecting the patient to learn whether they may be avoided or minimized (e.g., assuming excessive responsibility out of keeping with realistic goals; putting oneself at risk, such as dietary indiscretions for a type I diabetic). It is necessary to clarify and interpret the meaning of the stressor for the patient. For example, an amputation of the leg may have devastated a patient’s feelings about himself or herself, especially if the individual was a runner. It is necessary to clarify that the patient still has enormous residual capacity; that he or she can engage in much meaningful work, does not have to lose valued relationships, and can still be sexually active; and that it does not necessarily mean that further body parts will be lost. (However, it will also involve redirecting the physical activity to another pastime.) Otherwise, the patient’s perennial fantasies (“all is lost”) may take over in response to the stressor (i.e., amputation), make the patient dysfunctional (at work, sex), and precipitate a painful dysphoria, anxiety reaction, or major depressive disorder.

Some stressors may elicit an overreaction (e.g., the patient’s attempted suicide or homicide after the abandonment by a lover). In such instances of overreaction with feelings, emotions, or behaviors, the therapist would help the patient put his or her feelings and rage into words rather than into destructive actions and gain some perspective. The role of verbalization and the joining of affects and conflicts cannot be overestimated in an attempt to reduce the pressure of the stressor and enhance coping. Recreational drugs and alcohol are to be discouraged.

Psychotherapy, medical crisis counseling, crisis intervention, family therapy, group treatment, cognitive-behavioral treatment, and interpersonal therapy all encourage the patient to express affects, fears, anxiety, rage, helplessness, and hopelessness to the stressors imposed (Pollin and Holland 1992). They also assist the patient to reassess reality in the service of adaptation. Following the example given above, the loss of a leg is not the loss of one’s life. But it is a major loss. Sifneos (1989) believed that patients with AD could profit most from brief psychotherapy. The psychotherapy should attempt to reframe the meaning of the stress, find ways to minimize it, and diminish the psychological deficit due to its occurrence. The treatment should expose the concerns and conflicts that the patient is experiencing; help the patient gain perspective on the adversity; and encourage the patient to establish relationships and to attend support groups or self-help groups for assistance in the management of the stressor and the self.

Wise (1988), drawing from his experience in military psychiatry, emphasized the variables of brevity, immediacy, centrality, expectancy, proximity, and simplicity (BICEPS principles). The treatment structure encompasses a simple straightforward approach dealing with the immediate situation at hand which is troubling the patient. The treatment approach is brief, usually no more than 72 hours (True and Benway 1992).

In another sample, interpersonal psychotherapy was applied to depressed outpatients with human immunodeficiency virus (HIV) infection and found to be useful (Markowitz et al. 1992). Some of the attributes of interpersonal psychotherapy are psychoeducation regarding the sick role; using a here-and-now framework; formulation of the problems from an interpersonal perspective; exploration of options for changing dysfunctional behavior patterns; and identification of focused interpersonal problem areas. Lazarus (1992) described a seven-pronged approach in the treatment of minor depression. The therapy includes assertiveness training, enjoyable events, coping, imagery, time projection, cognitive disputation, role-playing, desensitization, family therapy, and biological prophylaxis.

Support groups have been demonstrated to help patients adjust and enhance their coping mechanisms, and they may enhance a sense of well being (Spiegel et al. 1989). However, findings showing group psychological intervention and lessened mortality have not been confirmed in at least two replication trials reported to date (Cunningham et al. 1998, Goodwin et al. 2001). Group therapy in the form of support groups have also been used in patients with AD. These groups help patients enhance their coping mechanisms (Fawzy et al. 1993, Spiegel et al. 1989). Though studies looking at the survival benefits of psychosocial group interventions have been mixed and show at most modest benefits, improvements in mood, distress level, and overall quality of life in cancer patients who attend support groups are very well documented (Goodwin et al. 2001, Newell et al. 2002).

Another therapeutic modality, eye movement desensitization and reprocessing (EMDR) has been recently studied in patients with AD (Mihelich 2000). EMDR, a psychotherapeutic technique shown to be effective in the treatment of PTSD, was carried out on nine patients suffering from AD. Results showed significant improvement in patients with anxious or mixed features but not in those with depressed mood. Additionally, those with ongoing stressors did not show improvement.

Akechi et al. (2004) investigated associated and predictive factors in cancer patients with AD and major depression. Findings revealed that psychological distress in these patients was associated with a variety of factors including social supports, physical functioning and limitations, and existential issues. Though the findings are not surprising, they do highlight the necessity of a comprehensive care plan for the treatment of AD that includes physical, psychosocial, and existential components. Though studies have yet to evaluate the potential role of family and couples therapy as well as alternative therapies such as acupuncture and yoga, based on these findings, there may well be a role for these modalities in the future treatment of AD.

In terms of randomized controlled trials (RCTs), a search of the Cochrane Database revealed only two RCTs on the specific psychotherapeutic treatment of AD. Gonzalez-Jaimes and Turnbull-Plaza (2003) showed that “mirror psychotherapy” for patients suffering from AD with depressed mood secondary to a myocardial infarction was both an efficient and effective treatment. Mirror therapy is described as a type of therapy with psychosocial, cognitive, and neurolinguistic components with a holistic focus. As part of the treatment, a mirror is used to
encourage patient acceptance of his/her physical condition that resulted from past self-care behaviors. In this study, mirror therapy was compared to two other treatments, Gestalt psychotherapy or medical conversation in addition to a control group. Depressive symptoms improved in all treatment groups compared with the control group, but mirror therapy appeared significantly more effective than other treatments in decreasing symptoms of AD at posttest evaluation.

In a second RCT, an “activating intervention” was carried out for the treatment of AD resulting in occupational dysfunction. One hundred ninety-two employees were randomized to receive either the intervention or care as usual (van der Klink et al. 2003). The intervention consisted of an individual cognitive behavioral approach to a graded activity, similar to stress inoculation training. Goals of treatment emphasized the acquisition of coping skills and the regaining of control. The treatment proved to be effective in decreasing sick leave duration and shortening long-term absenteeism when compared to the control group; both intervention and control groups, however, showed similar amounts of symptom reduction. This study formed the basis for the Dutch Practice Guidelines for the treatment of AD in primary and occupational health care (van der Klink and van Dijk 2003). These guidelines were prepared by a team of 21 occupational health physicians and one psychologist and subsequently reviewed and tested by 15 experts, including several psychiatrists and psychologists and 21 practicing occupational health physicians.

Though no other RCTs involving the psychotherapeutic treatment of pure cohorts of patients with AD could be found, many RCTs exist that studied an array of depressive and anxiety disorders and that included AD in their cohorts. For example, a recent trial comparing brief dynamic therapy (BDT) with brief supportive therapy (BSP) in patients with minor depressive disorders, including AD, was found in the Cochrane Database. Though both therapies proved efficacious in reducing symptoms, BDT was more effective at 6 months follow-up (Maine et al. 2005).

Pharmacotherapy

Though psychotherapy has historically been the mainstay of treatment for the AD, Stewart et al. (1992) emphasized the need to consider psychopharmacological interventions as well as psychotherapy for the treatment of minor depression, and this recommendation might be extrapolated to other subthreshold disorders. This group recommends antidepressant therapy if there is no benefit from 3 months of psychotherapy or other supportive measures. Although psychotherapy is the first choice treatment, psychotherapy combined with benzodiazepines may be helpful, especially for patients with severe life stress(es) and a significant anxious component (Shaner 2000, Uhlenhuth et al. 1995). Tricyclic antidepressants or bupropion were recommended in place of benzodiazepines for patients with current or past heavy alcohol use because of the greater risk of dependence in these patients (Uhlenhuth et al. 1995).

Psychotropic medication has been used in the medically ill, in the terminally ill, and in patients who have been refractory to verbal therapies. Rosenberg et al. (1991) described in the medically ill with depressive disorders (the type of depression was unspecified) that 16 of 29 patients (55%) improved within 2 days of treatment with the maximal dose of amphetamine derivatives. The presence of delirium was associated with a decreased response. Whether methylphenidate is similarly useful in AD with depressed mood remains to be examined. Reynolds (1992), reviewing randomized controlled trials, concluded that bereavement-related syndromal depression also appears to respond to antidepressant medication. The medication chosen should reflect the nature of the predominant mood that accompanies the AD (e.g., benzodiazepines for AD with anxious mood; antidepressants for AD with depressed mood). For example, Schatzer (1990) recommended that the therapist consider both psychotherapy and pharmacotherapy in the AD with anxious mood and that the psychiatrist prescribe anxiolytics as part of the treatment. Nguyen et al. conducted a double-blind randomized controlled trial to compare the efficacies of etifoxine, a nonbenzodiazepine anxiolytic drug, and lorazepam, a benzodiazepine, in the treatment of AD with anxiety in a primary care setting (Nguyen et al. 2006). Efficacy was evaluated on days 7 and 28 using the Hamilton Rating Scale for Anxiety (HAM-A). The two drugs were found to be equivalent in anxiolytics efficacy on day 28. However, overall more etifoxine recipients responded to the treatment. Moreover, 1 week after stopping treatment, fewer patients taking etifoxine experienced rebound anxiety, compared to lorazepam patients. The degree to which pharmacotherapy is used for AD has remained elusive. Olsson et al. (1998) report an increase in the use of antidepressants among less severely ill patients, including those with AD. However, Kaplan et al. (1994) suggest that those with less severe conditions are overall less likely to receive psychopharmacologic treatment.

Other authors have begun to examine the effect of homeopathic treatments. From a 25-week multicenter randomized placebo-controlled double-blind trial, a special extract from kava–kava was reported to be effective in AD with anxiety and without the adverse side effect profile associated with tricyclics and benzodiazepines (Volz and Kieser 1997). Tianeptine, alprazolam, and mianserin were found to be equally effective in symptom improvement in patients with AD and anxious mood (Ansseau et al. 1996). In a random double-blind study, trazodone was more effective than clorazepate in cancer patients for the relief of anxious and depressed symptoms (Razavi et al. 1999). Similar findings were observed in HIV-positive patients with AD (DeWit et al. 1999).

Hameed et al. (2005) in a retrospective chart review sought to determine if there was a difference in antidepressant efficacy in the treatment of major depressive disorder versus AD in a primary care setting. Patients had been prescribed mostly SSRIs. DSM-IV-TR symptoms, PHQ-9 depression rating scale scores, and functional disability reports were systematically used to assess the patient’s response. Results showed that neither depressed, nor AD patients demonstrated a difference in clinical response to any particular antidepressant. Patients with a diagnosis of AD, however, were twice as likely to respond to standard antidepressant treatment as depressed patients. This study suggests that antidepressants are very effective in treating depression in the primary care setting and may be even more effective in the treatment for AD with depressed mood.
Refactory Patients and Nonresponse to Initial Treatment

Those patients who do not respond to counseling or the various modes of psychotherapy that have been outlined and to a trial of antidepressant or anxiolytic medications should be regarded as treatment nonresponders. It is essential to reevaluate the patient to ensure that the diagnostic impression has not altered and, in particular, that the patient has not developed a major mental disorder, which would require a more aggressive treatment, often biological. The psychiatrist must also consider that an Axis II disorder might be interfering with the patient’s resolution of the AD. Finally, if the stressor continues and cannot be removed (e.g., the continuation of a seriously impairing chronic illness), additional support and management strategies need to be employed to assist the patient in optimally adapting to the stressor that she or he is confronting (e.g., experiencing the progression of HIV infection).

DSM-IV-TR allows the use of the diagnosis of AD even after 6 months, and then it is described as AD, chronic. With such a contingency (e.g., AD lasting a few years), it is necessary to ensure that the patient is not experiencing dysthymic disorder or an unremitting depressive disorder. However, these diagnoses have a symptom profile that should distinguish them from the AD.

Clinical Vignette 1

A 35-year-old married woman, mother of three children, was desperate when she learned she had cancer and would need mastectomy followed by chemotherapy and radiation. She was convinced that she would not recover, that her body would be forever distorted and ugly, that her husband would no longer find her attractive, and that her children would be ashamed of her baldness and the fact that she had cancer. She wondered whether anyone would ever want to touch her again. Because her mother and sister had also experienced breast cancer, the patient felt she was fated to an empty future. Despite several sessions dealing with her feelings, the patient’s dysphoria remained profound. It was decided to add antidepressant medication (fluoxetine, 20 mg/day) to her psychotherapy to decrease the patient’s continuing unpleasant symptoms. Two weeks later, the patient reported that she was feeling less despondent and less concerned about the future and that she had a desire to start resuming her former activities with her family. As the patient came to terms with the overwhelming stressor and assisted with antidepressant agents, her depressed mood improved, more adequate coping strategies to handle her serious medical illness were mobilized.

Although it is uncommon to use psychotropic medication for the majority of the ADs, this clinical vignette illustrates the effective use of antidepressant therapy in a patient who was not responding to counseling and psychotherapy; she never had symptoms that met the DSM-IV-TR criteria for a major depressive disorder. It has been found that the addition of a psychotropic medication in AD, on the basis of the mood disturbance, may assist those patients who continue to experience disordered mood and adjustment to the stressor despite treatment with verbal therapies. The antidepressant medications have also been found helpful in the terminally ill who exhibit AD with depressed mood and who have not responded to counseling alone.

Clinical Vignette 2

Mr. L illustrates the occurrence of an AD in response to the stressor of chronic illness and the loss of a body part essential to his usual occupational pursuit. Although bereavement is reserved for those patients who have lost a loved one, the loss of a body part or a body function constitutes a major stressor that can precipitate an AD. The patient’s “giving in” and “giving up” were unlike his customary extreme independence and resulted in a maladaptation to the stressor, out of all keeping with the physical limitations imposed by the surgery. It was also out of keeping with his family and cultural ideals that they kept going the “best they could” and maintained responsibilities and self-care even if it meant discomfort and extra effort.

Conclusion

Appropriate and timely treatment is essential for patients with AD so that their symptoms do not worsen; do not further impair their important relationships; and do not compromise their capacity to work, study, or be active in their interpersonal pursuits. Treatment must attempt to forestall further erosion of the patient’s capacity to function that could ultimately have grave and untoward consequences. Maladaptation may so impede the patient that irreversible losses in important sectors of his or her life may occur. Although this diagnosis lacks rigorous specificity, its treatment is no less challenging or less important. AD’s lack of a designated symptom profile results in this diagnosis having insufficient specificity. However, it is this lack of specificity, which permits the psychiatrist to have a “diagnosis” to use when the patient is presenting with early, vague, nonconcrete symptomatology, which should be noted, identified, and followed. This is similar to the situation with early fever, or fever of unknown origin, which, by the way, may never go on to a specific medical diagnosis, but be at discharge simply diagnosed as a “fever of unknown origin.” Unspecified chest pain is another example where the patient may never have a specific diagnosis even over time. Spitzer has described the ADs as a “wild card” in the psychiatric lexicon, that allows a place for an uncertain, early, not completely developed diagnosis to be housed until it develops into a full blown category, persists in a subsyndromal state, or disappears. As said above, this is not uncommon with physical or mental subsyndromal states.

DSM-III-R has been described as “medical illness and age unfair” (i.e., it does not sufficiently take into account the...
A 38-year-old woman who had lost her sister 5 days before in the attack on the World Trade Center was convinced that she was responsible for the sister’s death in that she did not stop by and have coffee with her that morning, thereby delaying her arrival at work which would have preserved her life. She was having difficulty sleeping, her diabetes was out of control, she found herself crying, unable to function at work, and having difficulty coping with her anxiety, depressed, and felt guilty that she was the only one who could have saved the sister, if she had not avoided her usual routine, which usually resulted in making the sister about 30 minutes late for her employment. The 30 minutes would have made the difference in arriving too late to enter the burning building. This patient did not have a posttraumatic stress response because it had not been 30 days since the stressor. She did not qualify for an acute stress disorder as she did not have derealization, depersonalization, or amnesia (i.e., at least 1 out of 5 symptoms are required). Could the patient be labeled as in bereavement? The patient has significant maladaptation to a major stressor characterized by a depressed and anxious mood. The degree of the patient’s belief that she was responsible for the sister’s death, and the degree of her nonfunctional capacity at work or to perform at home, does not support that bereavement would be a preferred diagnosis. Medications were prescribed to assist her with sleep and to reduce the daytime anxiety. What was the most appropriate diagnosis in the early days of this disaster, if the patient did not achieve the criteria for an acute stress response? It would seem that appropriate follow-up may highlight the trajectory of symptom development and whether the person goes on to develop other diagnoses or into a remission toward normalcy. Medications were temporarily prescribed to assist with the intense sleep and anxiety disturbances.

issues of age and/or medical illness (L. George, personal communication, Strain 1981). DSM-IV-TR has tried to take this into consideration with much effort and thought placed on those psychological interface disorders that border between physical and mental phenomena, for example, the somatoform disorders, AD, dissociation, and so on. However, in addition to enhancing reliability and validity, the psychiatric taxonomy needs to consider the impact of developmental epochs (e.g., children and youth, adults, young elderly, and “old” elderly) and medical illness on symptomatology. With regard to the latter issue, Endicott (1984) has described replacing vegetative with ideational symptoms when evaluating depressed patients with medical illness. Rapp and Vrana (1989) confirmed Endicott’s proposed changes in the diagnostic criteria for depression in medically ill elderly persons and observed maintenance of specificity and sensitivity, respectively, when substituting ideational for physical symptoms included more women, thus exhibiting a sex ratio resembling that for major depressive disorder or dysthymic disorder. Therefore, future editions of DSM may be able to take into account the differences encountered in symptom profiles for gender, various developmental epochs, and medical and psychiatric comorbidity.

Finally, longitudinal observations would describe the outcomes of AD over time. Their resolution, evolution to another diagnosis, their response to a variety of treatments would augment the understanding and approach to this important subthreshold diagnosis.

Comparison of DSM-IV/ICD-10 Diagnostic Criteria

In contrast to DSM-IV-TR (which requires the onset of symptoms within 3 months of the stressor), the ICD-10 Diagnostic Criteria for Research specify an onset within 1 month. Furthermore, ICD-10 excludes stressors of “unusual or catastrophic type.” In contrast, DSM-IV-TR allows extreme stressors so long as the criteria are not met for posttraumatic or acute stress disorder. ICD-10 also provides for several different subtypes, including “brief depressive reaction” (depressive state lasting 1 month or less), “prolonged depressive reaction” (depressive state lasting up to 2 years).

Section VI • Disorders

Everybody has a personality, or a characteristic manner of thinking, feeling, behaving, and relating to others. Some persons are typically introverted and withdrawn, while others are more extraverted and outgoing. Some persons are invariably conscientious and efficient, whereas others might be consistently undependable and negligent. Some persons are characteristically anxious and apprehensive, whereas others are typically relaxed and unconcerned. These personality traits are often felt to be integral to each person’s sense of self, as they involve what persons value, what they do, and what they are like most every day throughout much of their lives.

Personality traits have long been the focus of considerable scientific research. Their heritability (Bouchard and Loehlin 2001), childhood antecedents (Caspi et al. 2005), temporal stability (Roberts and DelVecchio 2000), universality (Allik 2005) and functional relevance to work, well-being, marital stability, and even physical health (Ozer and Benet-Martinez 2006) have been well established across many studies. It is “when personality traits are inflexible and maladaptive and cause significant functional impairment or subjective distress [that] they constitute Personality Disorders” (American Psychiatric Association 2000, p 686). The American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR; American Psychiatric Association 2000), provides the diagnostic criteria for 10 personality disorders. Two additional diagnoses are placed within an appendix to DSM-IV-TR for criterion sets provided for further study (passive–aggressive and depressive). We begin this chapter with a discussion of the diagnosis, etiology, and treatment of personality disorders in general, followed by a discussion of these points for the 12 individual personality disorders.

**Personality Disorder**

**Definition**

A personality disorder is defined in DSM-IV-TR as “an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual’s culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment” (American Psychiatric Association 2000, p 686). DSM-IV-TR Criteria: Personality Disorder provides the DSM-IV-TR general diagnostic criteria for a personality disorder.

Personality disorder is the only class of mental disorders in DSM-IV-TR for which an explicit definition and criterion set are provided. A general definition and criterion set can be useful to psychiatrists because one of the most common personality disorder diagnosis in clinical practice is often the diagnosis “not otherwise specified” (NOS) (Verheul and Widiger 2004). Psychiatrists provide the NOS diagnosis
when they determine that a personality disorder is present but the symptomatology fails to meet the criterion set for one of the ten specific personality disorders. A general definition of what is meant by a personality disorder is therefore helpful in determining whether the NOS diagnosis should in fact be provided. Points worth emphasizing with respect to the general criterion set provided in DSM-IV-TR Criteria: Personality Disorder are discussed in the following sections on the differential diagnosis, assessment, culture, epidemiology, and course of personality disorders.

**Differential Diagnosis**

One of the innovations of DSM-III was the provision of a multiaxial system for clinical diagnosis (American Psychiatric Association 1980, Spitzer et al. 1980). Prior to DSM-III psychiatrists rarely diagnosed a personality disorder when a patient’s symptoms met diagnostic criteria for an anxiety, mood, psychotic, or other mental disorder. In an extensive, widely cited, and historically influential study of psychiatric diagnosis, Ward et al. concluded that psychiatric diagnoses were excessively unreliable and that the greatest basis of disagreement was determining “whether the neurotic symptomatology or the characterological pathology is more extensive or ‘basic’” (Ward et al. 1962, p 202). They criticized the assumption that a clinician must choose between a “neurotic condition” and a personality disorder when both in fact appeared to be present. A personality disorder will predate the onset of most other mental disorders and its presence is likely to have a considerable impact on the course, treatment, and even etiology of the other mental disorder (Dolan-Sewell et al. 2001, Millon et al. 1996). DSM-III, therefore, moved the personality disorders to a separate axis so that psychiatrists could diagnose both conditions “rather than being forced to arbitrarily and unreliably make a choice between them” (Frances 1980, p 1050). The multiaxial system does appear to have been successful in encouraging psychiatrists to no longer make arbitrary distinctions between personality disorders and other mental disorders (Loranger 1990). Ironically, however, the placement of the personality disorders on a separate axis may also have contributed to the development of false assumptions and exaggerated expectations concerning the distinctions between personality disorders and other mental disorders with respect to etiology, pathology, and treatment (Krueger 2005).
